Glossary

Alveolus A hollow cavity found in the [lung](#) where gas is exchanged between air and blood.

Angiotensin receptors A class of receptors that bind to the hormone [angiotensin II](#).

Corpus luteum The temporary mini-organ on the ovary left behind after ovulation. It generates hormones that are important in pregnancy.

Cytochrome P-450 [Proteins](#) used in the metabolism of a variety of chemical compounds.

Decidua The decidua is the portion of the [uterine](#) lining shed during menstruation and important during [pregnancy](#).

Deiodinases Protein enzymes that remove an iodine from a thyroid hormone molecule.

Epigenetics Heritable changes in gene activity without changes in gene sequence.

Hematopoietic The formation of blood cellular components.

Hemodynamic The forces that regulate the flow of blood through the body.

Human chorionic gonadotropin A [hormone](#) produced by the [placenta](#) after [implantation](#).

Macronutrients The primary types of food containing carbon molecules that are used for fuel and chemical reactions in the body, including proteins, fats and carbohydrates.

Macrosomia Excessive birth weight on a newborn—typically defined as more than 4.0 kg at birth.

Microbiome The entire collection of microorganisms in a specific niche, such as the human intestine.

Peptide Short chains of [amino acids](#).

Polycythemia An excessive number of red blood cells in the circulation.

Preeclampsia A serious pregnancy complication characterized by high blood pressure and protein in the urine.

Nomenclature

$\dot{Q} = (P_{ao} - P_{ra}) / TPR$ Blood flow ($\dot{Q}$) is equal to the difference in blood pressure between the aorta (P_{ao}) and the right atrium (P_{ra}) divided by the total peripheral resistance (TPR).

$GFR = (P_{art} - \pi_{gc}) K_f$ The glomerular filtration rate (GFR) is the rate that blood is filtered by the glomeruli, the filtering units of the kidney, and is equal to the difference between arterial pressure (P_{art}) and osmotic forces (π_{gc}) caused by large molecules in plasma times the permeability coefficient (K_f) of the glomerular membrane.

$\dot{V}_E / \dot{V}_{O_2}$ The amount of pulmonary gas expired per minute ($\dot{V}_E$) divided by the rate that the body uses oxygen ($\dot{V}_{O_2}$), a measure of the efficiency of respiration.

Introduction

Female mammals have made physiological adaptations to their organ systems to provide a healthy environment for offspring as they grow in the uterus until birth. Raising offspring inside the body has its advantages. Nutrients for the embryo and fetus are derived from the mother's diet and from her tissue stores to provide a constant flow of nutrients across the placenta. This is in contrast to vertebrates that lay eggs where offspring are more vulnerable to predators. In addition, offspring can grow larger in the womb before being exposed to the external environment than would be possible in an egg. For example, a baby blue whale weighs about 3 tons at birth and is quite mature. It stretches the imagination to envision the size of an egg required to provide the space and total nutrients to care for such a fetus. The process of laying an appropriate sized egg might compromise the mother whale's wellbeing. In spite of advantages, carrying offspring in a uterus exacts a high physiological price for mothers to maintain the pregnancy.

Most of our knowledge regarding the physiology of pregnancy has come in the last 75 years but generalizations about changes in physiology must now be updated based on modern pregnancies. In the last quarter century, the physiology of pregnancy has changed dramatically because of the epidemic of obesity and diabetes mellitus. Patients with these conditions are now so commonplace they are no longer considered extraordinary in clinics where pregnant women are cared for and delivered. Obesity in pregnancy leads to risks for a number of complications and poor outcomes for offspring. The risks elevate as maternal fat mass increases (Yu et al., 2006). The condition of obesity leads to elevated risks for recurrent miscarriage, operative delivery, and preeclampsia. Offspring risks include perinatal mortality, obesity in later life (Yu et al., 2006) and congenital defects. The Institute of Medicine has made recommendations regarding weight gain during pregnancy because elevated weight gain has medical consequences (Fig. 1) (Nationalacademics.org,

Pregnancy Weight Gain Guidelines

Pre-pregnancy Body Mass Index (BMI)	Underweight <18.5	Normal Healthy 18.5 to 24.9	Overweight 25 to 29.9	Obese >30
	Recommended Weight Gain Range			
Pounds	28-40	25-35	15-25	11-20
Kilograms	12.5-18	11.5-16	7.5-11.5	5-9

Fig. 1 Guidelines for weight gain during pregnancy issued by the Institute of Medicine and the National Research Council (2009). IOM and NRC has recently issued new guidelines for weight gain during pregnancy. These guidelines were developed considering short- and longer-term outcomes for offspring. From Rasmussen, K. M. and Yaktine, A. L. (eds.) (2009). *Institute of Medicine. Weight gain during pregnancy: Reexamining the guidelines*. Washington, DC: National Academy Press. NATIONALACADEMICS.ORG 2013. Implementing guidelines on weight gain and pregnancy. <https://www.nap.edu/catalog/18292/implementing-guidelines-on-weight-gain-and-pregnancy>.

2013). Likewise, being born to a diabetic mother includes higher rates of preeclampsia, cesarean section, macrosomia, and neonatal hypoglycemia and polycythemia. Babies born to diabetic mothers are “programmed” to be vulnerable for childhood or adolescent obesity, type 2 diabetes mellitus, and heart disease (Simeoni and Barker, 2009).

Carrying a fetus to term exacts a physiological price on the mother. She undergoes profound changes in her organ systems and her organs function differently. Providing adequate energy and specific nutrients for the baby is a difficult task. It requires a healthy mother and a healthy placenta. It has become evident in recent years that the growth of fetuses is limited by placental capacity as well as by the mother’s ability to deliver nutrients to the placenta (Thornburg et al., 2000, 2015).

Metabolism

The basal metabolic rate (BMR) is the quantity of calories burned by the whole body per unit time at rest. It increases by some 30% over the course of pregnancy from about 1300 kcal/day to 1700 kcal/day (Butte et al., 2004). However, the relative and absolute change in BMR depends strongly on the pre-pregnancy body mass index (BMI = body weight/height²) and weight gain over gestation. This is shown in Fig. 2 (Butte et al., 2004). BMR was found to correlate with body weight, fat free mass, fat mass, cardiac output, maternal plasma insulin-like growth factor-1 concentration and thyroid hormone (T₃) concentration as well as fetal body mass. As individual organs adapt to their new role in supporting the pregnancy, their oxygen consumption rises. Thus, basal oxygen consumption increases most in the uterus to support the fetus but oxygen utilization rates are also increased in breast, kidney, heart, and respiratory muscles. As expected, total oxygen consumption in pregnancy increases in parallel to BMR and by some 50 mL O₂/min by term. Much of the energy cost is expended for augmenting ATP production. Extra energy is also required for generating heat, cellular processes, and to support added organ activity in kidney, heart, and breast.

Diet

Unlike pregnant bears, human females must consume food during pregnancy in order to provide for the nutrient needs of their offspring. Tissue turnover from a woman’s body is also important in providing nutrients. Thus, in early pregnancy when many

Fig. 3 Showing the maternal conditions that influence the health of the fetus and the outcomes suffered by the fetus when it reaches adulthood. From Chavatte-Palmer, P., Tarrade, A. and Rousseau-Ralliard, D. (2016). Diet before and during pregnancy and offspring health: The importance of animal models and what can be learned from them. *International Journal of Environmental Research and Public Health*, 13, with permission.

women become nauseated after eating food (hyperemesis or morning sickness), embryos are little affected if the mother had a healthy body preceding pregnancy. Bears on the other hand must gain all their weight before pregnancy so that they can hibernate over the entire course of gestation and provide nourishment to offspring in the uterus solely from maternal tissue stores.

One of the most profound discoveries made over the past quarter century is the role of maternal diet in affecting offspring health. While we know that the numbers and types of intestinal bacteria (microbiome) change during pregnancy, we do not know the degree to which individual components of the diet affect the microbe population in women who are pregnant. There is increasing evidence that bacteria live in the placenta and intestine of the fetus too. Preconception nutrition is also important because it provides nutrient stores for a woman that will become available during pregnancy. A healthy balanced diet or a “prudent diet” before and during pregnancy is associated with lower rates of cardiovascular disease and osteoporosis in offspring. See Fig. 3 (Chavatte-Palmer et al., 2016). The nourishment of eggs and sperm long before conception is important in offspring health. In spite of this new knowledge, little is known about how most nutrients actually affect fetal growth and development.

As for a non-pregnant woman, calories and nutrients are important for the pregnant mother to provide for the fetus and maternal tissues. Not only does the mother need a variety of nutrients for metabolism but foods high in methyl groups, like leafy green vegetables, are important for DNA and histone methylation, two “epigenetic” mechanisms by which gene expression is modified by diet. Specific nutrients or lack thereof, appear to impart epigenetic changes in tissues of both the mother and the fetus. Detrimental changes in gene expression may lead to disease vulnerability in offspring. Balanced macronutrient intake by the mother provides fuel for the baby as well as organic molecules that provide building blocks for organ development. Pregnant women need a balanced high fiber diet composed of whole grains, fruit, vegetables, nut, legumes and healthy oils, including vegetables and/or fish that contain omega three fatty acids (Fig. 4) (University, 2015). The omega three fatty acids, as found in most fish, are required for normal brain, retina and cardiovascular development. Some specific nutrients, like essential amino acids and fatty acids, are required for normal development because they have specific roles in building fetal organs.

Diet quality can be evaluated using the Healthy Eating Index, the Alternative Healthy Eating Index, and/or the Dietary Inflammation Index (Shivappa et al., 2014). Women who had a low-fat mass at conception generally gain more weight than women who had a large fat mass. Maternal diet also depends on the sex of the baby. Women carrying boys consume more calories per day from all macronutrient sources and gain more weight. Boys grow faster than girls and thus weigh more at birth. They do so while investing less in their placenta. Thus, boys have relatively smaller but more efficient placentas and a low fetal to placental weight ratio at birth. The consequence is that boys are more vulnerable to nutrient deprivation in the womb than are girls. The ratio of boys to girls being born during famine conditions can be reduced as boys are less likely to survive under such adverse conditions.

My Pregnancy Plate

Fig. 4 My pregnancy plate is a guide for pregnant women (or women planning to be pregnant) to assist in eating an optimal diet. Women should strive to eat from each plate quadrant during her main meals throughout the day. From OHSU Website: <http://www.ohsu.edu/blogs/doernbecher/files/2013/04/ohsu-my-pregnancy-plate.pdf>.

Heart and Blood Vessels

Of all the systems that change in response to pregnancy, changes in the cardiovascular system are the most profound. Adaptations are related to providing increases in blood flow to the kidney and uterus and having a vascular reserve in case of hemorrhage, especially at the time of delivery. Thus, a number of cardiovascular adjustments are found in normal pregnancies and are listed in **Table 1**. A recent meta-analysis of cardiovascular patterns confirms the patterns reported in the literature and in the table.

Table 1 Cardiovascular changes that occur in pregnancy

<i>Increased</i>	<i>Decreased</i>
Plasma volume	Pulmonary vascular resistance
Extracellular volume	Systemic vascular resistance
Red blood cell production rate	Hematocrit
Total red blood cell mass	Systemic arterial blood pressure
Uterine blood flow	Plasma albumin concentration
End diastolic dimension	Colloid osmotic pressure
Stroke volume	Arterial hydrogen ion concentration
Heart rate	Arterial carbon dioxide tension
Arterial oxygen tension	Platelet concentration
Venous capacitance	
Most clotting factors (fibrinogen, Factor VII)	

Blood Volume

Normal pregnancies are characterized by an increase in blood volume, with a less robust increase in red blood cell production rate which leads to a decrease in hematocrit. Thus, normal pregnant women are relatively anemic during pregnancy. While the low hematocrit is often described as caused by “hemodilution,” this cannot be the case. Rather, the set point for maintaining red cell mass appears to be lower during pregnancy. This makes sense from a hemodynamic point of view. The lowered red cell concentration lowers viscosity, improves flow through microvessels and lessens the systolic load for the left ventricle. Oxygen delivery to the uterus is maintained or augmented by the increase in cardiac output and blood flow to the uterus. Red blood cell production is augmented enormously during pregnancy while the life span of individual red cells is shortened. Under the influence of estrogen, progesterone, human placental lactogen and prolactin, hematopoietic stem cells take up residence in the spleen in addition to their normal home in bone marrow in pregnant mice which allows expansion of red cell production. This is likely to occur in human pregnancy also since the spleen is enlarged over the course of gestation.

Blood volume expansion of up to 50% begins early in pregnancy and is a requirement for a normal pregnancy. By 12 weeks of gestation plasma volume has increased by some 14% (Bernstein et al., 2001). Failure to expand blood volume during pregnancy has negative consequences for the fetus. One of the most profound changes is compromised blood flow to the uterus itself. Uterine blood flow is thought to increase 7- to 10-fold over the course of normal pregnancy. Doppler studies have shown that uterine flow velocity increases some 7-fold in normal humans as gestation proceeds. However, blood flow to the uterus may be compromised in mothers who do not expand their blood volume appropriately. In addition, mothers with hypertension may suffer similar decreases in uterine blood flow and reduced fetal growth. These conditions often lead to fetal growth restriction.

Heart

To provide greater blood flow to needy organs in a normal pregnancy, cardiac output is increased by augmenting both stroke volume and heart rate. Stroke volume is the volume of blood ejected from the heart each beat. Thus, the heart of the pregnant woman enlarges and the myocardium remodels so that stiffness is reduced. This remodeling is a major modification of the basic mechanical properties of the heart muscle; these changes mostly resolve in the weeks after delivery. Thus, during pregnancy, the chamber volumes are larger at any given transmural pressure than they were before the pregnancy. Fig. 5 (Poppas et al., 1997; Hunter and Robson, 1992) shows changes in stroke volume and cardiac output over the course of gestation. Fig. 6 (Poppas et al., 1997; Hunter and Robson, 1992) shows changes heart rate. Changes in mean arterial blood pressure and total peripheral resistance are shown in Fig. 7 (Poppas et al., 1997; Hunter and Robson, 1992). These changes are stimulated by increases in estrogen (Giraud et al., 1993). The timing of changes of hemodynamic factors can also be seen in the figures. Noteworthy is the fact that the stroke volume has already risen by 6–8 weeks post conception before the embryo has significant oxygen demands.

The quantitative aspects of these relationships can be visualized in the vascular adaptation of Ohm’s law in appropriate units. The cardiac output, $\dot{Q}$, is the flow per minute coming from the heart and is equal to the driving pressure, ΔP (P_{aorta} minus $P_{\text{right atrium}}$) divided by the total peripheral resistance (TPR). In other words,

$$\dot{Q} = (P_{\text{ao}} - P_{\text{ra}}) / \text{TPR}$$

Of the parameters in this equation, it is clear that the primary mechanism of increased cardiac output is the drop in total vascular resistance because ΔP decreases as blood pressure in the aorta is decreased. Stroke volume is increased, in part, because the heart chambers become larger at the same filling pressure and because the arterial blood pressure decreases and the arteries become more compliant. This makes it easier for the heart to pump a large volume of blood each beat.

Fig. 5 Stroke volume and cardiac output across the course of gestation. Blue bars = cardiac output (L/min). Green bars = stroke volume. Data from Hunter, S. and Robson, S. C. (1992). Adaptation of the maternal heart in pregnancy. *British Heart Journal* **68**, 540–543.

Fig. 7 Changes in mean arterial pressure and arterial compliance across pregnancy normalized to these parameters at 8 weeks post-partum. Blue bar = vascular resistance; green bars = arterial compliance. Data from Poppas, A., Shroff, S. G., Korcarz, C. E., Hibbard, J. U., Berger, D. S., Lindheimer, M. D. and Lang, R. M. (1997). Serial assessment of the cardiovascular system in normal pregnancy. Role of arterial compliance and pulsatile arterial load. *Circulation* **95**(10), 2407–2415.

Blood Vessels

Total peripheral vascular resistance is decreased with pregnancy. This involves two processes, remodeling of the arterial and arteriolar walls and active vasodilation of arterioles. The degree to which veins are remodeled, or made more compliant, in response to the changing hormonal environment is controversial. Because venous distension in the legs, varicose veins, hemorrhoids and ankle swelling are common complaints in pregnant women, but not before conception or after delivery, it is obvious that veins are more compliant as an adaptation to pregnancy (Edouard et al., 1998). Edouard et al. (1998) have argued that veins in the lower extremities are more affected than those in upper extremities. This remains to be seen. What is not controversial is the increase in a number of vasoactive agents in the maternal circulation. These include estrogen, nitric oxide, relaxin, and calcitonin gene-related peptide. It has been recognized for decades that the blood pressure elevating effects of angiotensin II (Ang II) are attenuated during pregnancy. This is likely due to a decrease in the ratio of type 1 angiotensin receptors (AT1R) to type 2 (AT2R) expressed in vascular smooth muscle. It is also true that arteries in pregnant animals are less constricted by alpha adrenergic agonists than in non-pregnant animals.

Hormones

There are several hormonal changes that accompany the more obvious hemodynamic changes during pregnancy. Progesterone is a key pregnancy-sustaining hormone. After 6–10 weeks gestation, the placenta is the major source of progesterone, producing up to 250 mg/day (Simpson and MacDonald, 1981). Estrogen and relaxin are critical hormones for the cardiovascular adaptations in pregnancy. They promote nitric oxide production. Relaxin, produced by the corpus luteum, placenta, and decidua, promotes

increased cardiac output and systemic arterial compliance and overall reduction in peripheral vascular resistance. Estrogens stimulate the synthesis of angiotensinogen by the liver, augmenting the renin increase observed in early pregnancy. Maternal plasma levels of atrial natriuretic peptide (ANP) and angiotensin II (Ang II) are elevated in pregnancy. ANP levels are elevated in response to atrial stretch as is evident by ANP increases in plasma when a woman is in the supine position. The effect is especially evident in the first trimester. Plasma levels of Ang II on the other hand, are more than doubled in the pregnant state. Although there is activation of the renin–angiotensin–aldosterone system early in pregnancy, which under non-pregnant conditions would cause vasoconstriction, there is a counterbalancing effect by progesterone, which has vasodilatory effects and is a potent aldosterone antagonist. These hormones promote vasodilation and sodium filtration on balance with the sodium-retaining properties of aldosterone and vasoconstrictive properties of Ang II.

Maternal thyroid hormone affects the development of the fetus. Human chorionic gonadotropin stimulates increases in thyroxine in maternal plasma early in pregnancy. Increased maternal plasma estrogen concentrations in early pregnancy stimulate an increase in thyroid hormone binding globulin which increases the capacity of maternal plasma to carry thyroid hormone. As term approaches, increased expression of deiodinases in the fetus under the influence of rising cortisol levels leads to an increase in fetal tri-iodo-L-thyronine (T3), the active form of thyroid hormone. Elevations in plasma and tissue levels of T3 lead to suppression of cardiomyocyte proliferation, maturation of the myocardium and pancreas. Thus, the mother and fetus work together to provide for the thyroid hormone needs of the developing embryo and fetus.

Kidney

The kidney undergoes enormous changes in response to pregnancy. Like the cardiovascular system, renal changes begin early in the pregnancy. The organs themselves change physically with an increase in length and volume under the internal influence of increased vascularity, interstitial volume and nephron hypertrophy (Lindheimer and Katz, 1992).

There are a host of physiological changes that underlie renal function in pregnancy. One of the most profound is glomerular filtration rate (GFR). GFR increases and peaks at 50% over non-pregnant values by the end of the first trimester (Baylis, 1999). The filtration rate of the glomeruli, when measured by inulin clearance, reaches up to 180 mL/min on average during pregnancy. The effective renal plasma flow also increases approximately 50% more than pre-pregnancy values by the third trimester.

Functional changes in the nephron during pregnancy include increases in urinary non-albumin protein excretion up to 260 mg/day. Urinary protein loss is considered normal if it remains below the arbitrary 300 mg/day. While some albumin is excreted in urine in normal pregnancies where <29 mg/day is considered the threshold for normal, the amount is amplified in women with preeclampsia. Loss of glucose in urine during pregnancy is also a normal condition, resulting from impaired glucose resorption in the collecting tubule and loop of Henle. Increased amounts of selective amino acids along with other nutrients are also lost in urine during a normal pregnancy.

The filtered load of sodium increases with increases in GFR during pregnancy. However, this is overcome by an augmented reabsorption of sodium by the renal tubule and increased secretion of aldosterone, deoxycorticosterone, and estrogen. The excess absorption of sodium ion is accompanied by retention of 1–2 L of water in the extracellular fluid volume. However, renin release and associated plasma renin activity are also increased during pregnancy due, in part, to decreases in arterial blood pressure and activation of the sympathetic nervous system as well as hormone actions including aldosterone.

There are many questions regarding functional changes in the kidney that remain unanswered. These include, what drives hemodynamic changes in the kidney, what mechanisms underlie increases in GFR, what regulates release of protein in the urine, and which vasoactive mediators that rise in concentration during pregnancy have a specific role in the kidney.

As mentioned, GFR and effective renal plasma flow increase in the pregnant woman. The same is true for most, if not all, mammals. In equation form, the forces that drive GFR are the difference between the transmural hydrostatic pressure across the glomerular capillary wall (ΔP) and the oncotic pressure (π_{cg}) in plasma.

$$GFR = (P_{art} - \pi_{cg})K_f$$

The quantification of filtration rate requires multiplication by a filtration constant (K_f) that represents both the hydraulic conductivity or “permeability” and the surface area of the glomerular membrane. Mathematical models of glomerular function suggest that hydrostatic pressure does not change appreciatively as blood travels down the capillary. However, the oncotic pressure does change as fluid is lost from the plasma as it moves down the capillary. An increase in renal plasma flow slows the increase in π_{cg} , maintaining the ΔP gradient and increasing the amount of fluid filtered. Thus, it appears that increased blood flow in the capillary is the primary driver of the increase in GFR in the pregnant state.

Respiration

There are a number of adaptations to pregnancy that improve the oxygenation levels in blood. The rate at which gas moves through the lung increases by 50% during pregnancy. Minute ventilation, $\dot{V}_E$ and alveolar ventilation, $\dot{V}_A$ are both increased in pregnant women. The increase in $\dot{V}_E$ is driven primarily by increased basal metabolic rate and plasma progesterone which affect the sensitivity of carbon dioxide in the respiratory centers in the brain stem. But other factors including plasma osmolality and concentrations of

ang II and arginine vasopressin also contribute (Heenan et al., 2001). Increased progesterone concentrations during the menstrual cycle are large enough to change the medullary set point for arterial P_{CO_2} in normal cycling women. In other words, women hyperventilate during the luteal phase of the cycle when progesterone levels are high, relative to the follicular phase when they are low. The same is true in experimental animals. Administration of progesterone to a rodent will cause an increase in alveolar ventilation even in male rodents. Women have a partial pressure of carbon dioxide in arterial blood of about 40 mmHg in menopausal years, about the same as for men. However, pregnant women have an increased respiratory drive that lowers their arterial gas pressure of carbon dioxide to about 32 mmHg or lower. This happens in spite of their increased metabolism and the production of CO_2 by the conceptus. Oxygen tensions in alveolar gas and arterial blood are determined by the difference between inspired partial pressure of oxygen and the partial pressure of carbon dioxide in alveolar gas. Thus increasing ventilation drives down the carbon dioxide tensions in the alveolar gas and increased pressure of oxygen in the lung. This increases the oxygen pressure in the arterial blood of the pregnant woman. The end result is that peripheral arterial PO_2 exceeds 100 mmHg at sea level, higher than in the non-pregnant state.

There are mechanical changes that occur in lung and chest wall as pregnancy proceeds. Tidal volume is increased by 40% early in pregnancy and is maintained. Functional residual capacity is decreased by some 20% as are its component volumes, expiratory reserve volume and residual volume. Total lung capacity is decreased by a few per cent. The forces at work include an increased respiratory drive which increases the depth of breathing and increases alveolar ventilation at normal breathing rates, and the reductions in functional residual capacity that occurs in response to the space occupying growing uterus against the diaphragm. These adaptations cause a mild respiratory alkalosis is normal in pregnancy. Oxygen levels in the arterial blood are maintained for the fetus, and low carbon dioxide levels in maternal blood favor diffusion of CO_2 out of the fetal compartment. The price the mother pays is more labored breathing which many women notice especially late in gestation.

Exercise

Exercise during pregnancy has not only proven to be safe, but it is beneficial to the mother, fetus, and placenta (Anon, 2006). Exercise improves cardiovascular function, suppresses pregnancy weight gain, decreases musculoskeletal discomfort, reduces muscle cramps and lower limb edema, improves mood stability, decreases preterm birth, increases neonatal lean body mass, and expands placenta volume. Many of the physiological aspects of exercise in pregnancy are similar to those found in non-pregnant women. Most of the physiological responses to exercise during pregnancy that are distressing are found in women who were sedentary before pregnancy or in fit women late in their third trimester. As mentioned above, heart rate and alveolar ventilation rate are higher in pregnant women than in non-pregnant women. Thus for any given exercise work load these parameters remain higher for pregnant women. The ventilatory equivalent for oxygen ($\dot{V}_E/\dot{V}_{\text{O}_2}$) is higher in pregnant women at similar non-pregnant workloads. In late gestation, pregnant women may have lower concentrations of glucose during and following prolonged exercise. In addition, pregnant women maintain a lower body temperature and higher blood pH levels than non-pregnant women.

For obese pregnant women, the response to exercise has not been well studied and the few existing studies are contradictory. It is known that in non-obese women, the maximal oxygen consumption ($\dot{V}_{\text{O}_{2\text{max}}}$) declines as a function of gestational weight gain when expressed per unit of body mass. In all normal men and women, a net lactate production occurs during graded exercise at the work load when they cross the so-called “ventilatory threshold.” At workloads beyond the threshold, ventilation rate trajectory increases more dramatically. For reasons that are not completely known, the peak blood lactate levels in women who are pregnant are lower than in non-pregnant women (Heenan et al., 2001). Possible explanations include greater dilution by the expanded blood and extracellular fluid volume in pregnancy and lactate consumption by the fetus. The latter makes sense because the fetal heart and kidney use lactate as their preferred fuel. Another fact is that the capacity for making lactate appears to be compromised in pregnant women.

Placenta

Data from several sources have shown that the shape of the placenta is a marker for disease risk in offspring. The more that placental shape veers from being round, the higher the risk for cardiovascular disease, preeclampsia, and some cancers. It appears that placental size and shape are most predictive of offspring health if maternal phenotype is taken into account. For example, babies born to shorter than average women with very small or very large placentas are more vulnerable for acquiring disease in adulthood than those born to taller women.

Drug Metabolism

Drugs are carried in the blood and metabolized differently in women who are pregnant. Oral drugs may reach the blood stream more slowly because of reduced gut motility believed to be due to elevated plasma progesterone levels. Once in the blood stream drugs dilute into a larger volume of distribution because of the expanded extracellular volume. In addition, the concentrations of plasma protein to which many drugs are normally bound are reduced in pregnancy. Thus, unbound concentrations of drugs may be

increased in the blood compared to the non-pregnant state. On balance, the increased concentration of steroid hormones in the blood may displace drugs from their binding sites on circulating proteins and lead to a reduced biological half-life of the drug. Thus, each drug has to be considered independently because of different protein binding properties.

Obese women who are pregnant will have a higher fat mass in which lipid soluble drugs will distribute. However, this has been little studied in women who have a high fat mass, either in or outside of pregnancy. This should be taken into account when drugs are administered. On the other hand, hormones of pregnancy like estrogen and progesterone and their cousins will induce the expression of some members of the cytochrome P-450 system while other members will be inhibited. The take home message is that pregnancy changes the pharmacokinetics of most drugs. Many of these changes can be directly accounted for by changes in metabolic activity in the liver. Another reason that pregnant women may metabolize drugs differently than non-pregnant women is that drugs may be metabolized by the placenta or will cross the placenta and be metabolized by the fetus. Contrary to popular opinion, all drugs cross the placenta in detectable amounts. Large lipid insoluble molecules cross the placenta very slowly by diffusion. Highly lipid soluble molecules cross the placenta by diffusion very rapidly because they instantly cross the lipid bilayer of the maternal facing placental membrane and thus have the entire surface area of the placenta available for diffusion. The placenta has its own molecular system to de-toxify some molecules and this helps protect the fetus from further damage.

Conclusion

Nearly every organ of a woman's body is modified by the changes in the hormonal environment found during pregnancy. The cardiovascular system is dramatically modified in favor of delivering oxygen and nutrients to the fetus through augmented blood flow to the uterus. The increased rate and depth of breathing ensure better oxygenation of blood. Physical exercise is beneficial to both mother and baby. Yet, there are many aspects of pregnancy changes that we do not understand. These include changes in individual organs like pancreas, spleen, brain, and placenta that have not been thoroughly investigated.

Glossary

Corpus luteum A transient, hormone-secreting ovarian structure that develops from a ruptured follicle after ovum release but degenerates unless pregnancy occurs.

Decidualization Differentiation of the endometrium in preparation for pregnancy in rodents and primates.

Implantation The process of attachment of the early embryo to the maternal uterine wall.

Paracrine Type of cell-to-cell communication whereby a cell produces a signal that targets nearby cells.

Placenta Temporary endocrine organ of pregnancy that allows for transport of nutrients, gasses, and waste between mother and fetus.

Pubic symphysis Cartilaginous joint connecting the left and right pubic bones.

Relaxin A 6-kDa polypeptide hormone secreted primarily by corpora lutea that promotes reproductive tract growth and connective tissue remodeling in preparation for birth.

Introduction

Relaxin was discovered more than 90 years ago by Frederick Hisaw who found that serum from pregnant guinea pigs promoted relaxation of the interpubic symphysis of virgin guinea pigs. Relaxin was later isolated from the sow corpus luteum and identified as a hormone of pregnancy that relaxes uterine smooth muscle and connective tissue of the reproductive tract during the latter half of pregnancy in preparation for birth, hence its name. Subsequently, research to isolate, purify, and characterize relaxin from reproductive tissues in multiple species led to an understanding of the structure, chemistry, and biological actions of the hormone. A new chapter in our understanding of relaxin opened up in the late 1990s and early 2000s with the discovery of relaxin family peptide (RXFP) receptors and ligands, the generation of relaxin and relaxin receptor null animals, and the production of recombinant human (H2) relaxin. These discoveries provided important information about relaxin target tissues and mechanisms of action and revealed new roles for the hormone that extended beyond the female reproductive tract. Relaxin is now recognized to target both reproductive and nonreproductive tissues, in males and females. This hormone acts as a neuropeptide in the central nervous system, as an antifibrotic agent in tissue remodeling and as a vasodilator in the cardiovascular system. Relaxin has a wide variety of physiological roles in pregnancy that are species dependent. The targets of relaxin include the pubic symphysis, uterus, cervix, vagina, and mammary glands; and relaxin is a key modulator of cardiovascular changes associated with pregnancy. This chapter focuses on the structure, sources, and biological actions of relaxin during the cycle, in the early embryo, during implantation, and in early pregnancy as well as the impact of relaxin on reproductive tract remodeling and on the cardiovascular system in late pregnancy.

Relaxin and the Relaxin Receptor

Relaxin Structure

Relaxin is a member of the relaxin family of peptide hormones, with structural similarity to insulin and insulin-like growth factors. It is synthesized as a single chain, preprorelaxin, whose signal A-peptide is cleaved to form prorelaxin. The C-chain of prorelaxin is subsequently targeted by convertases to form the native 6-kDa relaxin hormone, consisting of an A and B chain connected by two disulfide bonds and another intra-A chain disulfide bond. In humans and higher primates, there are three relaxin genes (*RLN1*, *RLN2*, *RLN3*), which generate H1, H2, and H3 relaxin peptides, respectively. In rodents, there are two forms of the gene (*Rln1*, *Rln3*) while other mammals have one (*Rln1*) with the exception of ruminants (e.g., sheep and cattle) that lack a *Rln1* gene. The human *RNL2* gene and the *Rln1* gene in other species generate the form of relaxin protein detected in the circulation during pregnancy. While the amino acid sequence of relaxin differs markedly across species, the receptor binding region of the B-chain, amino acids 13–20 (Arg-X-X-X-Arg-X-X-Ile/Val), is highly conserved and required for biological actions of relaxin.

Relaxin Receptor and Mechanism of Action

Given relaxin's structural similarity to insulin, it was thought that relaxin receptors would be similar to the tyrosine kinase-containing receptors that bind insulin and insulin-like growth factors. However, the long-awaited discovery of the relaxin receptor in 2002 revealed it to be a guanine nucleotide binding protein (G-protein)-coupled receptor, related to the family of receptors for

glycoprotein hormones including follicle stimulating hormone, luteinizing hormone, and thyroid stimulating hormone. As illustrated in Fig. 1, the relaxin receptor, now identified as the relaxin family peptide (RXFP)1 receptor, consists of a large extracellular domain containing 10 leucine-rich repeats (LRR) important for high-affinity binding of relaxin and a low-density lipoprotein a (LDLa) module needed for signaling. A lower affinity relaxin binding site is found in the extracellular loops (ECL) of the seven-transmembrane domain that is linked to a C-terminal endodomain. Unlike the heterogeneity of relaxin proteins across species, sequence analysis of RXFP1 receptors shows a high degree of conservation. For example, human and rodent orthologues of RXFP1 show greater than 90% sequence similarity.

The RXFP1 receptor has a wide tissue distribution. Both mRNA and protein for RXFP1 have been identified in female reproductive tissues including the ovary, uterus, cervix, vagina, placenta, and mammary gland as well as in males, in the prostate and testes. In addition, nonreproductive tissue targets expressing RXFP1 receptor include parts of the brain, heart, kidney, liver, lung, and blood vessels. Studies on the mechanism of relaxin action are complicated by the variety of signaling pathways activated in different cell types by the hormone including cyclic adenosine monophosphate (cAMP), mitogen-activated protein kinase, tyrosine kinase, and nitric oxide (NO) pathways. Relaxin activates the adenylate cyclase-cAMP-protein kinase A (PKA) system in reproductive tissues including the mouse interpubic ligament, rat myometrium, and human endometrium. Studies in uterine stromal cells indicate that the cAMP response to RXFP1 activation involves the protein kinase C pathway and tyrosine kinase activity, unlike other G-protein coupled receptors. In addition, there is evidence that actions of relaxin in the heart and blood vessels, as well as the anti-fibrotic effects of relaxin in tissue remodeling, involve the NO synthase-NO-cyclic guanine monophosphate (cGMP) pathway. Taken together, these studies indicate that in response to relaxin, a variety of signaling pathways may be activated including increases in phosphorylation of multiple kinases that may be target tissue-dependent.

Fig. 1 Structural features of the relaxin family peptide receptor RXFP1. The RXFP1 receptor consists of a large extracellular domain connected to a transmembrane domain via a hinge region. The extracellular domain consists of (A) a leucine-rich repeat (LRR) region that contains the primary high-affinity binding site for relaxin. Connected to the LRR region is (B) an NH₂-terminal, low-density lipoprotein receptor type A (LDLa) module, which is required for signaling. (C) The extracellular loops (ECL) of the transmembrane domain contain a lower affinity binding site for the peptide. Relaxin family peptides and their receptors. *Physiological Reviews* **93**, 405–480.

Sources and Secretion of Relaxin

Ovarian Relaxin

While sources of relaxin are species-specific, relaxin is a product of the corpus luteum in most mammalian species. The corpus luteum of pregnancy is a rich source of relaxin in pigs, rodents, and humans. There is also evidence that relaxin is expressed in large, granulosa cell-derived luteal cells of the corpus luteum of the cycle in these species. Relaxin protein and/or transcripts have also been identified in theca interna cells of developing follicles in both humans and pigs. Also, gonadotropin-induced luteinization of both theca interna cells and granulosa cells is linked to increased relaxin production. Human granulosa-lutein cells collected during *in vitro* fertilization protocols produce relaxin in culture.

Placental Relaxin

The placenta is also a source of relaxin during the second half of pregnancy for many mammals including dogs, cats, rabbits, hamsters, horses, and humans. An increase in circulating relaxin in dogs and cats is used as a diagnostic aid for pregnancy detection based on the increase in systemic relaxin produced by the placenta within 3–4 weeks after mating. In the mare, microcotyledons of the placenta express relaxin transcripts after the first trimester of pregnancy and secrete relaxin into the circulation. Systemic relaxin levels decline in mares with placental insufficiency or other placental disorders. In addition, there is evidence that the early equine embryo expresses relaxin transcripts, although secretion of relaxin has not been verified. In women, evidence for both H1 and predominantly H2 gene expression has been found in decidual and placental tissues. The uterus is a primary source of relaxin in pregnant guinea pigs, and there is evidence for relaxin production by the uterine epithelium in both rats and pigs. Relaxin is also detectable in milk of several species including rats, dogs, pigs, and humans. The detection of higher concentrations of relaxin in milk than in the maternal circulation suggests that relaxin is either produced locally by the mammary gland or made elsewhere and concentrated in milk. Detection of relaxin protein and/or relaxin transcripts in mammary tissues of rats, guinea pigs, pigs, and women supports the idea of a local source for relaxin in milk.

Relaxin Secretion

Relaxin levels are low to undetectable in the circulation of nonpregnant animals. In pregnancy, relaxin circulates in the blood of all mammals, but the pattern of relaxin secretion differs markedly across species. For example, in pregnant pigs, relaxin is detectable at low levels in the circulation and marked by a large prepartum surge (over 100 ng/mL) just prior to parturition. In rodents, serum relaxin levels are relatively constant until the end of pregnancy, when there is a marked surge in relaxin secretion just before parturition. In the mare, serum relaxin rises in the first trimester of pregnancy and remains elevated until foaling. Following delivery of the placenta, relaxin levels are undetectable in the circulation of the postpartum mare suggesting that the placenta is the main source of circulating relaxin in the horse. In contrast, in humans and other primates, serum relaxin is highest in early pregnancy and peaks (1 ng/mL) near the end of the first trimester, after which relaxin levels decline and remain low for the duration of pregnancy. In pregnant women, luteal relaxin is the source of systemic relaxin as illustrated in ovum-donation pregnancies in which circulating relaxin is not detectable in the absence of functioning ovaries. In contrast, human placental/decidual relaxin is thought to act locally in a paracrine manner, playing an important role in controlling fetal membrane remodeling at the time of parturition.

Biological Actions of Relaxin in Female Reproduction

Biological actions of relaxin differ markedly across species, as evident in [Table 1](#). During the cycle and in early pregnancy, relaxin actions include ovarian follicular growth and remodeling, implantation and decidualization, and myometrial quiescence. Later in pregnancy, a role for relaxin has been proposed in uterine growth, remodeling the birth canal and fetal membranes in preparation for parturition, and mammary gland development. Additionally, relaxin is involved in changes in the cardiovascular system and in fluid homeostasis as pregnancy progresses.

Follicular Growth and Remodeling

While relaxin is best known for its actions during the latter half of pregnancy, the expression of ovarian relaxin in nonpregnant animals during the estrous cycle supports a role in ovarian function. Although systemic relaxin is not detectable during the follicular phase of the cycle in any species, relaxin levels in follicular fluid increase with follicular size in pigs, suggesting local production and action of relaxin in the follicle. Relaxin has been implicated in follicular growth in pigs, humans, and rats. In pigs, low doses of relaxin promote the growth of granulosa and theca cells *in vitro*. Consistent with these observations, relaxin binding sites have been localized in both granulosa and theca cells of developing porcine follicles. Given the importance of proteolytic remodeling for follicular wall rupture, a paracrine role for relaxin in ovulation was suggested based on evidence in several species. Relaxin increases secretion of proteolytic enzymes, including plasminogen activator and collagenase, in rat follicular cell cultures. In the *in vitro* perfused rat ovary, human relaxin-2 induces ovulation. Human granulosa cells from all follicle sizes express the RXFP1 receptor, and incubation with relaxin increases vascularization of human follicular tissues. On the other hand, there is no evidence

Table 1 Biological Actions of Relaxin in Female Reproduction

<i>Tissue</i>	<i>Rat</i>	<i>Mouse</i>	<i>Pig</i>	<i>Human/ Nonhuman primate</i>
Ovary	Follicular growth Ovulation		Follicular growth	Follicular growth Vascularization
Uterus	Uterine growth Reduced collagen density Vasodilation Inhibition of myometrial contractions Decreased duration of labor	Uterine growth Reduced collagen density Vasodilation Inhibition of myometrial contractions	Uterine growth Tissue remodeling Inhibition of myometrial contractions Decreased duration of labor	Decidualization Angiogenesis Increased endometrial thickness

^aRelaxin's effects tested in patients with heart failure only.

Data summarized from work reviewed by Sherwood, O.D. (2004). Relaxin's physiological roles and other diverse actions. *Endocrine Reviews* **25**, 205–234 and Conrad, K.P. (2011). Maternal vasodilation in pregnancy: the emerging role of relaxin. *American Journal of Physiology Regulatory, Integrative and Comparative Physiology* **301** (2), R267–R275.

for a role for relaxin in follicular growth or ovulation in mice. Administration of relaxin failed to increase mouse preantral follicular growth. In addition, studies in both relaxin-null and RXFP1 knockout mice confirm that both groups of mice are fertile and litter sizes are comparable to wild-type controls. Taken together, these studies reinforce the observation that relaxin's action differs across species. Further research is needed to confirm a role for relaxin in ovulation.

Implantation

Evidence for a role for relaxin in implantation comes from studies in nonhuman primates and women. Here, highest circulating levels of relaxin occur in the first trimester of pregnancy in comparison to other species, including rodents, pigs, and horses, in which relaxin levels are maximal at the end of pregnancy. Administration of relaxin and estrogens to ovariectomized, nonpregnant marmoset monkeys increased endometrial thickness and angiogenesis. Similar results were observed following relaxin treatment in a model of early pregnancy in the rhesus monkey and during peri-implantation in the cynomolgus macaque. In addition, relaxin targets RXFP1 receptors expressed in human endometrial cells to increase production of hormones and growth factors involved in decidualization and angiogenesis, important for implantation. Decidualization of the endometrial stroma creates a receptive environment for blastocyst implantation, and there is evidence that relaxin is important for initiating this process in nonhuman primates and in women. The decidual response is characterized by increased expression of two biological markers: insulin-like growth factor binding protein 1 and prolactin. Relaxin is produced by human decidual cells and can induce decidualization of endometrial stromal in culture. Additionally, administration of relaxin in the rhesus monkey resulted in increased resident lymphocytes and maintained connective tissue integrity in the endometrium, processes necessary for establishment of pregnancy. Taken together, these studies show effects of relaxin on the human and nonhuman primate endometrium of early pregnancy that support a role for relaxin in implantation in these species. However, clinical observations in women indicate that implantation and pregnancy still occur in the absence of a corpus luteum or detectable serum relaxin. Whether locally produced relaxin can support implantation is unknown, and confirmation of paracrine effects of relaxin in promoting implantation await further study.

Uterine Growth and Remodeling

Multiple studies have reported uterotrophic effects of relaxin in nonpregnant rodents, pigs, and primates. Growth-promoting effects of relaxin include water imbibition as well as increased DNA content and proteins involved in structural changes in the uterus such as collagen, gap junction proteins, and matrix metalloproteinases. In prepubertal pigs, uterotrophic effects of relaxin include increases in uterine dry weight, protein and DNA content. In rats and mice, relaxin treatment increases endometrial thickness, reduces densely packed collagen fibers, and dilates uterine blood vessels. In a similar manner, the vagina is a target for the growth-promoting actions of relaxin in rodents and pigs. Concurrent with uterine growth is a relaxin-induced increase in endometrial angiogenesis in rhesus and marmoset monkeys, and an increase in vascular endothelial growth factor (VEGF) by human endometrial stromal cells has been reported. In human endometrial cells, the angiogenic response to relaxin is menstrual-cycle specific in that incubation with relaxin increases VEGF secretion in the secretory phase but not in the proliferative phase. The angiogenic effects of exogenous relaxin were

demonstrated in clinical trials for scleroderma in which women who were treated for 24 weeks with relaxin experienced an increased incidence of irregular and/or heavier-than-normal menstrual bleeding compared to placebo-treated women.

These results led to the hypothesis that relaxin induces uterine growth during pregnancy to accommodate the growing fetus. In support of this hypothesis, relaxin deficiency in early pig pregnancy resulted in a 30% reduction in uterine wet weight compared to controls. Further, relaxin increased uterine growth during pig pregnancy. In the pig, VEGF is produced by endometrial stromal cells *in vitro*, and relaxin increased VEGF secretion from endometrium collected on days 10–12 of pregnancy. In contrast, relaxin is not required for uterine growth during rodent pregnancy. Relaxin immunoneutralization in rats during the second half of pregnancy did not affect uterine weight at term. Likewise, relaxin knockout mice had similar uterine weights throughout pregnancy as compared to wild-type controls.

Myometrial Quiescence

Relaxin decreases myometrial contractility in pregnancy, but this effect is species-specific. In rodents and pigs, relaxin inhibits spontaneous and oxytocin-induced smooth muscle contractions conducive to implantation and preventing premature delivery. Rats ovariectomized in early pregnancy and supplemented with ovarian steroids exhibited increased uterine contractile frequency compared with controls. When hormone replacement therapy included relaxin, uterine contractile activity returned to normal. Further, data in rats indicate that relaxin's effects on the myometrium may also contribute to the spacing of embryos. *In vitro* experiments in rats and pigs suggest that progesterone increases myometrial sensitivity to relaxin, synergistically reducing uterine contractions. In rats, relaxin attenuates myometrial contractions partially through activation of cAMP/PKA signaling. In humans, relaxin does not inhibit spontaneous or oxytocin-induced myometrial contractility, although human myometrial cells *in vitro* do generate cAMP in response to relaxin via RXFP1 signaling (as in other species), suggesting that myometrial quiescence is stimulated by signaling factors downstream of cAMP.

The physiological role of the prepartum surge in relaxin to maximal levels in rats, mice, and pigs just prior to parturition is not well understood. It has been suggested that relaxin helps to coordinate contractions at the onset of delivery in these species but relaxin-deficient rodents do not have altered timing of labor onset. Several studies have determined that relaxin does play a role in the duration of delivery and live birth rates. In pigs and rats made relaxin-deficient in the second half of pregnancy, duration of labor increased and live birth rates decreased compared with controls.

Connective Tissue Remodeling of the Pubic Symphysis and Cervix

In guinea pigs, mice, and bats the pubic symphysis transforms from fibrocartilage to a flexible ligament prior to parturition. Relaxin's ability to remodel connective tissue of the guinea pig pubic symphysis of pregnancy led to discovery of the hormone in 1926, and similar effects in mice supported the development of a mouse interpubic ligament bioassay for relaxin. As expected in relaxin-null mice, interpubic ligament length and weight are reduced in comparison to wild-type mice. The significance of relaxin-induced pubic symphysis remodeling in late pregnancy may be species dependent. Studies show that the substantial increase in interpubic ligament length observed in late-pregnant mice is not required for delivery. Parturition in relaxin knockout mice is normal, and they deliver their pups as rapidly as their wild-type littermates. Relaxin-induced interpubic ligament elasticity in guinea pigs and mice is estrogen-dependent, but this pelvic joint transformation does not occur in all species late in pregnancy. There are reports of pelvic joint laxity in women during the first half of pregnancy when relaxin levels are elevated but whether endogenous relaxin contributes to pelvic joint laxity in pregnant women is unknown.

Cervical growth and softening are well-known effects of relaxin in late-pregnant rats and pigs. Relaxin-induced cervical growth during late pregnancy involves an increase in both weight and size of the cervix. Studies show that relaxin-induced proliferation of epithelial and stromal cells, as well as inhibition of cervical cell apoptosis, are responsible for these trophic effects. The characteristic increase in cervical elasticity and softening near the end of pregnancy in rats and pigs involves dispersion of collagen fibers and remodeling of the extracellular matrix that changes the tensile strength of the cervix. In fact, these cervical modifications failed to appear following ovariectomy of pregnant pigs and rats but returned following relaxin replacement therapy. The cervix in relaxin-deficient rats, pigs, and knockout mice remains small and firm, with collagen fiber bundles failing to disperse. Cervical softening is estrogen-dependent in rats but not in pigs. Debate exists about whether relaxin mediates human cervical softening. While cervical softening can be induced in women with direct application of pig relaxin to the cervix, similar results were not observed in clinical trials using recombinant human relaxin-2. However, in women there is evidence for a role for decidual relaxin acting locally, in a paracrine manner, to stimulating proteolytic enzyme degradation of fetal membranes near the time of delivery.

Mammary Gland and Nipple Development

Relaxin promotes mammary gland development during pregnancy in several species. Its major effect in pigs is on the mammary parenchyma while in rodents nipple development is affected. In pigs, mammary gland development begins around day 80 of pregnancy and continues until parturition, corresponding to increasing systemic estrogen and relaxin levels. Relaxin replacement in ovariectomized pigs stimulated mammary gland parenchyma growth through reduction in collagen fiber bundles. Similar effects on mammary collagen fiber bundles were observed in rats and mice, where relaxin was also shown to reduce the length of elastin

fibers and increase the cross-sectional area of arterioles. Relaxin-binding sites have been identified in mammary tissues of rats, pigs, and humans.

Studies in relaxin-null mice and in rats made relaxin-deficient by immunoneutralization revealed that the hormone is required for development of mammary nipples, which occurs in the latter half of pregnancy. The mammary glands of relaxin and RXFP1 knockout mice are normal and produce milk, but these dams have such small nipples at term that pups are unable to suckle and die. In contrast, the nipples of relaxin-deficient pigs are fairly well developed at term and nursing pigs can obtain milk. Given that relaxin is detectable in milk of several species in levels greater than observed in maternal circulation, it is possible that relaxin is acting in an autocrine or paracrine fashion on mammary tissues during late pregnancy.

Maternal Vascular Adaptations

Studies indicate that relaxin plays an important role in regulating cardiovascular changes during pregnancy. This includes pregnancy-related increases in plasma volume, cardiac output, and vasodilation as well as reductions in systemic vascular resistance and blood pressure. In nonpregnant rats, relaxin administration results in cardiovascular changes similar to those observed in pregnancy, including increased cardiac output, decreased systemic vascular resistance, and increased renal filtration rate and plasma flow. In pregnant rats made relaxin-deficient early in pregnancy, maternal vascular adaptations fail to occur at mid-pregnancy. Further, in relaxin-deficient, pregnant rats, uterine blood vessel elasticity is reduced and renal and systemic vascular resistance is increased, similar to nonpregnant rats. In humans, similar maternal vascular changes also occur during the first trimester, when relaxin levels are maximal.

Relaxin is a potent vasodilator of blood vessels in both reproductive and nonreproductive tissues; however, this effect is vessel-specific. For example, in humans, in vitro relaxin treatment relaxed precontracted gluteal arteries but did not affect small pulmonary resistance arteries, uterine myometrial arteries, or placental stem villus arteries. In addition, the impact of relaxin on blood vessels includes both rapid and sustained vasodilatory responses. The rapid response to relaxin in dilating blood vessels involves RXFP1 binding, PI-3 kinase activation, and NO production. The slower, sustained vasodilatory response to relaxin involves generation of NO, matrix metalloproteinase production, and endothelin receptor binding. Of note is that these vasodilatory effects of relaxin, together with actions to increase cardiac output, provide the basis for clinical trials testing the efficacy of relaxin in treatment of cardiac failure.

During pregnancy in humans and rodents, a decline in plasma osmolality occurs without a concomitant decrease in antidiuretic hormone, thereby reducing the osmotic threshold. Studies in rats and mice suggest that relaxin plays a role in this adaptation during pregnancy. Reduced osmolality in the second half of pregnancy in rats and mice corresponds with an increase in circulating relaxin in this period. Plasma osmolality declines following relaxin infusion in nonpregnant rats, although there was no reduction in osmolality in relaxin-deficient pregnant rats. Whether relaxin plays a role in the reduction of plasma osmolality in human pregnancy is not clear. Plasma osmolality declines in women with ovum-donation pregnancies in which circulating relaxin is undetectable. Relaxin's effects on plasma osmolality during pregnancy in the rat may be due, in part, to alterations in water consumption. During late pregnancy, drinking increases in rats. Relaxin treatment by intravenous or intracerebroventricular injection results in water consumption within minutes in nonpregnant rats. Further, relaxin removal in rats via passive immunization during the second half of pregnancy reduces drinking frequency.

Conclusions

The diverse actions of relaxin in reproductive tissues across a variety of species supports its characterization as a pleotropic hormone. Advances in identifying the sources and biological actions of relaxin in female reproduction reviewed here preceded the discovery of the cognate receptor for relaxin in 2002. Subsequently, studies in relaxin-deficient animals have shed new light on the biological actions of relaxin in both reproductive and nonreproductive tissues. The widespread tissue distribution of the RXFP1 receptor has led to investigation of new roles for relaxin in the brain and cardiovascular system, as well as in fibrosis and wound healing. In terms of reproduction, fundamental questions about the control of relaxin synthesis, its mechanism of action, and significance of local vs. systemic relaxin production and action in reproductive tissues will continue to be important areas of investigation.

Structure and Evolution

Oxytocin is a small peptide hormone comprising just nine amino acids arranged in a cyclic form (**Fig. 1**) held together by a single cystine sulphhydryl bridge between amino acids 1 and 7. Together with the modified C-terminal amino acid, this gives it a resistance to rapid degradation in the blood stream as well as providing a unique three-dimensional structure which complements the hormone-binding pocket of its receptor (see later). It also offers a specific surface with which to interact with its binding protein, neurophysin 1. In all mammals oxytocin is very closely associated with the structurally related hormone vasopressin. Both derived by gene duplication from a common invertebrate ancestral hormone, probably much like the molecule annetocin in worms. Both vasopressin and oxytocin have retained aspects of their ancestral physiology: annetocin is responsible for the contractility and function of the mesonephric duct linking the coelomic cavity with the outside, thereby helping to convey gametes out of the body and maintaining osmotic balance. In modern mammals, oxytocin is still linked with the contraction of the uterus and the vas deferens, and vasopressin with maintaining osmotic balance in the kidneys. However, during evolution, both hormones have also acquired a number of other functions, which have led to increasing subtlety in their regulation as well as in the expression and regulation of their specific receptors.

One of the more interesting aspects in the evolution of oxytocin is the way in which the gene which encodes it is strongly related to the gene for vasopressin. In all vertebrates, both genes are separated by only a few nucleotides from one another. Most genes following gene duplication tend to diverge both spatially across the genome and in terms of their sequence. The opposite is true for oxytocin and vasopressin. One explanation is that by being so closely linked they can more easily exchange genetic information

Fig. 1 Schematic diagram to illustrate the structure of the oxytocin gene and its derived mRNA transcript. The oxytocin mRNA is translated to yield a single polypeptide precursor comprising in order a signal peptide to aid translocation to the cellular secretory apparatus, and the oxytocin peptide itself, followed by the tripeptide Gly-Lys-Arg which acts as a cleavage signal for intracellular enzymes as well as a donor of an amide group the C-terminal end of the oxytocin peptide. This is followed by the larger neurophysin 1 carrier protein. The lower panel shows a three-dimensional representation of the oxytocin peptide indicating how the cysteine bridge between amino acids 1 and 6 maintains a rigid shape to the molecule.

with each other in a process called gene conversion, which encourages the encoded proteins to be more similar to one another and conserved.

Like vasopressin, oxytocin is encoded as part of what is called a polyprotein, comprising more than one functional unit (Ivell and Richter, 1984a). Besides oxytocin, the gene also encodes a larger cysteine-rich polypeptide called neurophysin 1, which acts as a carrier protein for oxytocin. The vasopressin gene similarly encodes not only vasopressin but also neurophysin 2. The two carrier proteins are very similar and both can bind their associated peptide hormones with high affinity. Oxytocin mRNA encodes a pre-pro-polyprotein (Fig. 1), which because of an N-terminal signal peptide is first translocated from the ribosome into the lumen of the endoplasmic reticulum, where this is removed to make the pro-polyprotein; this is then transferred to the Golgi apparatus and finally to acid-rich secretory vesicles. During this process specific proteolytic enzymes separate the oxytocin from the neurophysin and ensure transamidation of the oxytocin C-terminus, although the oxytocin remains associated with its neurophysin carrier protein until released from the cell.

Oxytocin Expression—Cells, Tissues, and Organs

The principal site of oxytocin synthesis is within the large magnocellular neuroendocrine neurones (MCNs) of the hypothalamus within the brain. These MCNs are arranged symmetrically close to the third ventricle in two groups (Fig. 2), the supraoptic nucleus (SON) and the paraventricular nucleus (PVN), and can produce either oxytocin or vasopressin. The MCNs, of which there are only a few thousand in both nuclei, are characterized by long axons which project downwards out of the hypothalamus, along the pituitary stalk, with endings from which the hormone is released within the posterior lobe of the pituitary gland, also called the neurohypophysis (Fig. 2). In addition, secretory granules containing oxytocin may also be released from the cell bodies and especially dendrites within the hypothalamus, often projecting to more distant parts of the brain (Pow and Morris, 1989). Moreover, the PVN also contains smaller, so-called parvocellular neurones which express oxytocin and project elsewhere in the hypothalamus or to the brainstem and spinal cord (Armstrong, 1995; Brown et al., 2013).

The MCNs are responsible for the oxytocin which is released from the posterior pituitary in a pulsatile fashion and is responsible for the key oxytocin-dependent physiologies of uterine contraction at birth, the milk let-down response during lactation, and smooth muscle contraction of the male tract during copulation (see below). However, oxytocin is also produced locally within

Fig. 2 Diagram to show the location of the pituitary gland on the underside of the human brain, beneath the hypothalamic region (inset). The paraventricular nucleus (PVN) and the supraoptic nucleus (SON) each comprising several thousand magnocellular neuroendocrine cells (MCN), are indicated by ovals. Their beaded axons extend through the pituitary stalk to end in the posterior pituitary where oxytocin is released into the bloodstream. The anterior pituitary and associated hypophyseal portal system are also illustrated. Modified from Breckwoldt M, Neumann F, Brauer H (1991) *Exempla endokrinologica*, Band 1, Medical Service Munchen, Germany, pp. 1–173.

several organs and tissues where it appears to serve paracrine regulatory roles. These include the testes, follicular and luteal cells in the ovaries (see below), the thymus, placenta and probably other tissues (Ivell and Russell, 1995).

Regulation of the Oxytocin Gene

The gene for oxytocin is located on chromosome 20p12.2 in humans and is very small comprising altogether only about 1000 nucleotides made up of three exons and two intervening sequences (Fig. 1). Particularly the region of exon 2, encoding most of the neurophysin moiety, is highly homologous with the equivalent region of the vasopressin gene. In terms of regulation, there is still relatively little known about the region responsible for determining cell specificity, although experiments in transgenic mice indicate that this resides within only a few thousand nucleotides from the transcription start site. In vivo, the oxytocin gene can be modulated by circulating steroid hormones, in particular estradiol and testosterone seem able to cause an up-regulation of the gene, for example to increase synthesis and secretion of oxytocin in late pregnancy. Whilst some of this effect may be due to indirect effects of the steroids on the cells which make oxytocin, in vitro studies have shown that activation of estrogen and androgen receptors can directly increase the transcriptional activity of the oxytocin gene. However, this is mediated in an unconventional way, which does not require a direct interaction between the steroid receptor and the oxytocin gene promoter region. Instead, it has been shown that activated steroid receptors work through another transcription factor called steroidogenic factor 1, which interacts with a specific responsive element at –160 nucleotides upstream of the transcription start site (Ivell et al., 2014). In fact, mutation of the DNA-binding domain of a steroid receptor such that it can no longer interact with DNA does not prevent the steroid-dependent up-regulation of the oxytocin gene. Moreover, there is no potential responsive element within several thousand nucleotides of the transcription start site which exhibits the potential to directly interact with a steroid receptor. This non-classical activation of the oxytocin gene by steroid receptors also allows for regulation by selective estrogen receptor modulators (SERMs), such as tamoxifen which, at least in an in vitro cell system, stimulates the oxytocin gene, rather than being an antagonist as in the classical estrogen-dependent pathway (Ivell et al., 2014).

Oxytocin Synthesis and Secretion

The MCNs are highly active cells receiving informational input from a wide range of brain regions, including the hypothalamus, the limbic region, and the brainstem (Leng et al., 1999). Mostly such inputs are either excitatory or inhibitory, employing glutamate or GABA neurotransmitters, respectively, particularly where these derive from within the hypothalamus. Here there is direct input from the arcuate, suprachiasmatic and tuberomammillary nuclei. Additionally MCNs express receptors for a wide range of peptides and other neurotransmitters, such as serotonin, dopamine or acetylcholine (Brown et al., 2013). Neuronal input also comes from more distant regions such as the subfornical organ or the organum vasculosum of the lamina terminalis. These are so-called circumventricular organs which lack a blood-brain barrier, hence allowing reception of many informational molecules in the blood, including other hormones. There are also significant projections to the MCNs from the nucleus tractus solitarius and ventrolateral medulla, which receive signals from peripheral tissues involving the vagus nerve. This informational route includes the important sensory afferents from the mammary glands and the uterus, as well as coordinating appetite-regulating peptides such as cholecystokinin (CCK) from the gastrointestinal tract or cytokine immune signals.

Within the MCNs oxytocin is packaged into secretory vesicles. These can be transported to or released from any part of the neurones, including axon swellings and undilated axons, and also from the dendrites and the cell bodies themselves (Morris and Pow, 1991). It is important to distinguish between oxytocin released axonally from the posterior pituitary and that which is released within the brain, mostly via dendrites. Such secretion is regulated differentially. Whereas release from axon terminals occurs largely via electrical action potentials (spikes), that from dendrites or from cell bodies is consequent on intracellular Ca^{2+} release from stores in the endoplasmic reticulum (Ludwig and Leng, 2006).

Although the neurosecretion of oxytocin or vasopressin is the main role of MCNs, they also release, particularly within the hypothalamus, many other signaling molecules, including the peptides CCK, dynorphin, galanin, apelin and secretin. They can also generate NO via nitric oxide synthase, as well as endocannabinoids and adenosine. These local informational molecules serve in an autocrine/paracrine way to orchestrate and modulate MCN function.

Release of oxytocin from dendrites does not necessarily occur synchronously with axonal release. Such responses may be to the same stimulus, but on a different time-scale, or dendritic release may be completely independent of axonal release from the pituitary. For example, in lactating rats oxytocin is secreted within the SON before it is secreted from the pituitary; in contrast, upon hyperosmotic stimulation the sequence is reversed. One role for oxytocin released within the hypothalamus appears to be to act as part of a feedback loop auto-regulating MCN electrical function (Ludwig and Leng, 2006; Ludwig and Stern, 2015). Dendritic oxytocin causes release by the MCNs of intracellular Ca^{2+} independently of electrical activity, thereby priming the cells for subsequent oxytocin release by moving secretory vesicles close to the cell surface. This priming effect serves to amplify and co-ordinate the dendritic release of oxytocin and hence the overall activity of the MCNs within a nucleus.

Oxytocin Receptor, Expression and Regulation

Although the oxytocin peptide and its effects were known for many years, it was the work of the Japanese scientist Tadashi Kimura which in 1992 finally led to the identity and structure of the oxytocin receptor (Kimura et al., 1992). The oxytocin receptor belongs to the class A group of 7-transmembrane domain G-protein-coupled receptors. It has only a short N-terminal extracellular domain and the hormone effectively interacts with all of the exposed extracellular regions of the receptor. These regions may also be differentially glycosylated though whether this is important for regulation is not known. Once the hormone has bound, a conformational change in the receptor leads to activation of an inhibitory G-protein and hence a PI3-kinase-linked signaling pathway leading to intracellular Ca^{2+} release. Importantly, the oxytocin receptor responds to activation by oxytocin by rapid desensitization and internalization as is typical for most hormones which are secreted in a pulsatile fashion (Arrowsmith and Wray, 2014). Up regulation of the oxytocin receptor system in a cell either requires a delay in the desensitization process or simply an increase in the expression of the oxytocin receptor gene. This is what happens, for example, at term of labor in women when oxytocin receptor gene transcripts appear to be increased almost 100-fold. However, the responsiveness of the oxytocin receptor may also be modulated by changing the properties of the cell membranes in which it is anchored. For example, increasing the rigidity of the plasma membrane by increasing its cholesterol and possibly also its steroid (e.g., 17OH-progesterone) content attenuates the intracellular response (Gimpl et al., 2002).

There is a single gene encoding the oxytocin receptor, located on chromosome 3p25 in the human, which is highly homologous across species. The gene comprises three exons. In spite of the importance of the oxytocin receptor for the induction of labor and mammary function, surprisingly little is known about the transcriptional regulation of the oxytocin gene. It is certainly regulated by steroids such as estrogens, though probably in a non-classical manner, whereby activated estrogen receptors act indirectly via other transcription factors within the upstream promoter region of the gene. Other specific transcription factors such as MafK are also involved, acting within an intron of the receptor gene. Moreover, DNA methylation within different regions of the gene also appears to correlate with cell specificity of expression. To date, however, we still have very little understanding of the precise molecular mechanisms invoked when the receptor is either up- or down-regulated (Kimura et al., 2013). Our lack of understanding is exacerbated by the evident physiological redundancy in some functions, so that, for example, oxytocin receptor knockout mice appear to undergo parturition normally.

Oxytocin, Uterine Contraction and Parturition

Oxytocin is one of the most potent uterotonic factors known, a property which is used today in the induction of birth (see below). Shortly before the end of pregnancy (term), as estrogen concentrations rise and there is functional progesterone withdrawal, oxytocin receptors are up-regulated in the myometrial smooth muscle layers of the uterus, and become sensitive to the increasing pulses of oxytocin coming from the posterior pituitary and released locally from reproductive tissues (Summerlee, 1981; Russell et al., 2003). Labor and birth represent a series of positive feedback loops whose resultant has to be the expulsion of the uterine contents. Part of this involves the induction in term myometrium of local prostaglandin-F2 α expression, which like oxytocin causes smooth muscle contractility by mobilizing intracellular Ca^{2+} stores. The influence of factors which have promoted myometrial quiescence, such as the hormone relaxin in most species (though not in humans) and progesterone decreases, as is the placental production of the oxytocin-degrading enzyme oxytocinase. Uterine contractility, along with fetal movements, elicits the *Ferguson reflex*, whereby neuronal afferents from the cervix via the vagal system result in further activation of the MCNs in the hypothalamus.

In rats and other species, oxytocinergic MCN give rise to intense synchronized bursts of electrical activity which cause the release of increasingly large secreted pulses of oxytocin (Fig. 3). Pulsatility is important since a continuous and sustained secretion of oxytocin would not only quickly deplete cellular stores of the hormone, but would lead to a desensitization of the oxytocin receptors and a slowing of the birth process. This activation of the MCNs also leads to an increase in the dendritic secretion of oxytocin, which, as mentioned above, would effectively influence neuronal plasticity to further orchestrate and increase the oxytocinergic function of the magnocellular nuclei. High prevalent estrogen levels would also act to stimulate oxytocin gene transcription in the MCN, presumably via estrogen receptor- β , which is known to be expressed in these cells. Interestingly, in cows at term additional oxytocin is produced in pulses by the ovarian corpus luteum which otherwise is relatively quiescent during the second half of gestation.

As in other aspects of reproductive physiology, there is a degree of redundancy in this system. While transgenic mice in which either oxytocin or its receptor have been inactivated still appear to give birth normally, lack of the prostaglandin-synthesizing enzyme COX2 does lead to a disruption of labor and birth, apparently due to a down-regulation of the oxytocin receptor in the uterus. Moreover, the oxytocin-deficient mice do appear to have lost some of the circadian control of birth, suggesting that the oxytocin system is still critical for the precise timing of the birth process (Ratajczak and Muglia, 2008).

Within the hypothalamus there are further adaptations to pregnancy and birth. Largely based on studies in rats it has been shown that in the latter half of pregnancy there is an up-regulation of the κ -opioid dynorphin within the MCNs. This feeds back on the MCNs to suppress electrical activity and maintain the pool of stored oxytocin, and is supported by increased GABAergic activity to further suppress MCN activity. With the onset of uterine contractions, noradrenergic neurones which are stimulated by the vagus system, together with the co-expressed μ -opioid enkephalin, directly activate the MCNs, leading to a release of both axonal and

Fig. 3 Pulsatile appearance of oxytocin in the blood of a pregnant cow in the day prior to and of parturition, as indicated. Oxytocin was measured every 15 min and corresponding behavior was noted. From Fuchs AR, Ivell R, Ganz N, Fields MJ, Gimenez T (2001) Secretion of oxytocin in pregnant and parturient cows: corpus luteum may contribute to plasma oxytocin at term. *Biol Reprod.* 65:1135–1141, with permission.

dendritic oxytocin (Leng et al., 2008; Hatton and Wang, 2008). The latter then causes an amplification of the MCN response (see above) and uterine contractility accelerates.

It is important to note that oxytocin is not only involved in the expulsion of the fetus at birth, but also subsequently of the placenta, and then critically ensures the contraction of the empty uterus and constriction of blood vessels to prevent undue blood loss. Therapeutically, oxytocin may be given to support this process, if not before.

Oxytocin and Lactation

Lactation naturally follows birth, and thus takes advantage of the already active and primed oxytocinergic MCNs. Although not involved in mammary gland development, nor in milk synthesis and secretion, transgenic mouse studies have shown that oxytocin is essential for the so-called *milk let-down reflex*: hypothalamic oxytocin is released from the posterior pituitary in response to suckling at the nipples, causing contraction of the smooth muscle cells surrounding the mammary alveoli and release of milk. As in the uterus, oxytocin receptors are increasingly expressed in the myoepithelial cells of the developing alveoli towards the end of pregnancy, and their responsiveness to oxytocin also increases. Studies in rats indicate that there are short bursts of electrical activity every 5–15 min in the MCN leading to pulses of oxytocin release from the posterior pituitary and release of milk to the suckling pups (Lincoln and Wakerley, 1974), even though these are persistently attached to the nipples for much longer periods. This appears to be a common feature in all mammals and recent imaging in humans has shown a similar intermittent milk-release in response to continuous suckling. As for uterine contractility, oxytocin receptors in the mammary gland appear to become desensitized if

exposed to continuous oxytocin delivery, and seem to require relatively high concentrations of oxytocin within a pulse, together indicating that such burst pulsatility is both essential and efficient.

Oxytocin and Natriuresis

The oxytocin-producing MCNs, like those making vasopressin, are also osmoreceptors and respond to increased osmotic pressure by secretion of oxytocin. But unlike in uterine contractility and lactation here oxytocin seems to be produced in a more sustained fashion with circulating levels increasing but without evident pulsatility. In animal models it has been shown that oxytocin can directly stimulate the kidney to increase Na^+ excretion (natriuresis), presumably via oxytocin receptors, though possibly also via vasopressin V1 receptors with which oxytocin can weakly interact. However, much of this effect in vivo appears to be due to the stimulation of cardiac atrionatriuretic peptide secretion, which in turn influences the kidney. There appears to be some species specificity in the natriuretic response, with humans and dogs exhibiting little effect compared to rodents.

Oxytocin and Satiety

It is known that cholecystokinin (CCK) can stimulate hypothalamic oxytocin secretion via CCK receptors on vagal efferents from the stomach. Since CCK is produced by the duodenum following a meal, these vagal actions evidently mediate a satiety reflex. Then experimentally it has been shown in rats that injection of oxytocin into the brain can suppress appetite. Taken together these findings strongly suggest that CCK can reduce appetite by activating the release of dendritic oxytocin in the brain.

Oxytocin and Copulation

The oxytocin-dependent induction of smooth muscle contractility in the reproductive system is not limited to female mammals. Also in male mammals there is good evidence that pulses of oxytocin can be measured accompanying the contraction of smooth muscle cells in the epididymis and vas deferens associated with ejaculation (Ivell et al., 1997). Nothing is known, however, about the mechanisms involved in inducing such oxytocin pulsatility. This has been shown in rodents, bulls and humans. Additionally, it is believed that oxytocin produced locally within the testes is responsible for the slow peristaltic contractility of the seminiferous tubules associated with sperm release from the seminiferous epithelium. Centrally within the hypothalamus, oxytocin also appears to promote penile erection (Argiolas and Melis, 2013), though whether this is due to dendritic release of oxytocin from MCNs or from parvocellular oxytocinergic neurones in the PVN is not clear.

Oxytocin and the Maternal Recognition of Pregnancy

Although it has been shown that oxytocin is made locally at low concentration within the ovary of several mammalian species, including humans, monkeys, pigs and rodents, only in ruminants such as cows and sheep is this expression amplified to assume the function of a novel endocrine system. In cows, oxytocin is synthesized in large amounts by the granulosa cells of the growing antral follicle shortly before ovulation (Ivell and Richter, 1984b). After the oocyte is released, these cells differentiate further to become the large luteal cells of the new corpus luteum. Both oxytocin mRNA and peptide continue to be accumulated within these luteal cells throughout the luteal phase of the oestrous cycle with only limited amounts being secreted into the blood stream in a pulsatile fashion. The majority of oxytocin is only released towards the end of the oestrous cycle upon stimulation by the prostaglandin- $\text{F}_{2\alpha}$ secreted at that time by the uterine epithelium and only if there is no pregnancy (Fig. 4). This prostaglandin- $\text{F}_{2\alpha}$ also causes the induction of the process known as luteolysis, whereby the corpus luteum, which up until now has been making all of the progesterone of the female cycle, involutes to become a small corpus albicans and progesterone production ceases. If there is a pregnancy, luteolysis must be prevented so that the corpus luteum can continue to make the progesterone essential for supporting the pregnant uterus and early embryo.

The process by which this happens is called the *maternal recognition of pregnancy* (MRP) and in ruminants the oxytocin–oxytocin receptor system plays a central part (Hansen et al., 1999). Firstly, the oxytocin released from the corpus luteum activates oxytocin receptors on the endometrial epithelium of the uterus (Fig. 4), these in turn cause the activation of prostaglandin-producing enzymes, such as cyclooxygenase 2 (COX2), as well as ensuring that the end-product is prostaglandin- $\text{F}_{2\alpha}$ rather than the related prostaglandin- E_2 which has opposing effects on cells. If a pregnancy occurs, the early ruminant embryo begins to produce a peptide called interferon-tau in large amounts already by day 16 of the luteal phase and reaching a maximum at around the time when luteolysis would normally be occurring at the end of the non-pregnant cycle. This interferon interacts with interferon receptors also on the uterine epithelial cells, which in turn suppress the expression of the oxytocin receptors on the same cells, and therefore effectively interrupts the positive feedback loop between ovarian oxytocin production and uterine prostaglandin- $\text{F}_{2\alpha}$ expression. The precise mechanisms how interferon achieves the suppression of the oxytocin receptors is still unclear. In sheep it appears

Fig. 4 Schematic diagram (upper panel) to illustrate the oxytocin-dependent feedback loop between the corpus luteum of the ovary and the uterine lining at the end of the non-pregnant oestrous cycle in cows (see text for details). The indicated PGF2 α , which causes luteolysis, is mimicked pharmacologically when oestrous cycles are artificially terminated before the normal time by injection of the drug cloprostenol (a PGF2 α analogue) in order to induce precisely timed cycles for artificial reproduction in a process called synchronization. Lower panel: when an egg is fertilized, the resulting early embryo (blastocyst) begins to produce the trophoblast hormone interferon-tau (IFN τ) which, acting on interferon receptors, causes the down-regulation of the oxytocin receptor in the uterine lining. At the same time it switches prostaglandin production from the luteolytic PGF2 α to the luteotrophic PGE2.

that this may involve the suppression of estrogen receptors which support the expression of the uterine oxytocin receptors. In dairy cows, it would appear that interferon-tau specifically induces in the epithelial cells so-called interferon-responsive factors which act directly to inhibit the gene encoding the oxytocin receptor. In addition to this down-regulation of the oxytocin receptor, the interferon also appears to cause a switch in prostaglandin production from prostaglandin-F2 α to prostaglandin-E2. In this way luteolysis is prevented and pregnancy continues to be supported by ovarian steroids.

Although there may be a role for oxytocin and oxytocin receptors in endometrial function in other species, only in ruminants do we see this high ovarian expression of oxytocin and explicit involvement in MRP.

Oxytocin and the HPG Axis

Oxytocin not only has effects directly on receptors within the reproductive organs themselves, but it also appears to be able to influence the hypothalamo-pituitary-gonadal (HPG) axis (Evans, 2002). Activation of oxytocin receptors on the gonadotropin-producing cells of the anterior pituitary causes activation of phosphoinositide-3-kinase and intracellular Ca^{2+} release, together therefore interacting with the GnRH-induced signaling activity in the same cells. Whether this oxytocin *in vivo* arrives like GnRH via the portal system from the hypothalamus or comes from the posterior pituitary is not known, but it does suggest that the hormones of the HPG axis can be modulated at times of high oxytocin expression, for example at the end of pregnancy or during lactation.

Behavioral Effects of Oxytocin

Since oxytocin is largely unable to cross the blood–brain barrier, the various behavioral effects of oxytocin must be due to centrally released hormone, possibly from the dendrites of the MCNs. Moreover, such effects do not correlate with levels of oxytocin measured in blood, and these do not reflect the levels in cerebrospinal fluid.

There is no doubt that central oxytocin is responsible for a range of maternal and affiliative behaviors (Ivell and Russell, 1995; Hammock and Young, 2006; Leng et al., 2008; Neumann and Landgraf, 2012). For example, in sheep oxytocin induces the bonding of a new-born lamb with its mother. In the female prairie vole it promotes monogamous pair-bonding. It is generally described as “anti-anxiolytic,” encouraging more exploratory and olfactory behavior in laboratory animals. It is also linked to sexual responsiveness and behavior in female and male rats, respectively. Finally, it appears to be released centrally in response to food rewards and satiety.

There have been numerous claims of similar effects in humans, though possibilities for therapeutic approaches using oxytocin in certain mental disorders are very limited due to the difficulty of targeting the brain for a peptide which cannot cross the blood–brain barrier. Although it has been proposed that oxytocin applied as a nasal spray might circumvent this difficulty by directly reaching the brain across the nasal mucosa, the findings from such studies are not without substantial controversy (Leng and Ludwig, 2016).

Oxytocin Pharmacology and Clinical Use

The main pharmacological use of oxytocin to date has been in the field of obstetrics. The potential of oxytocin for stimulating uterine contractions can be traced back to the early experiments of Sir Henry Dale (1906) and the founder of the Royal College of Obstetricians and Gynecologists, Professor William Blair Bell (1909) who used extracts of the infundibular body (the pituitary stalk connecting the hypothalamus to the pituitary) to stimulate rabbit uterus contraction *in vitro*. Blair Bell first employed oxytocin to increase blood pressure and induce uterine contractions. The effect on the uterus was more profound and maintained than seen for blood pressure so Blair Bell starting using it to treat atonic uterus and postpartum hemorrhage. Following this, and the sequencing and synthesis of oxytocin in 1953, the use of synthetic oxytocin (Brand name, Syntocinon) for induction and augmentation of labor became embedded in clinical practice. Oxytocin was also used in combination with ergometrine to manage the third stage of labor (delivery of the placenta) and prevention of postpartum hemorrhage. However, the introduction into mainstream clinical practice was not based on any randomized clinical trial of syntocinon versus placebo, rather by consensus following a large case series of 1000 primigravida pregnancies in which 120 were given an intravenous infusion of oxytocin (from 5 drops to 50 mU per minute) as part of an active management strategy (O’Driscoll et al., 1969). In the United Kingdom, standard (low dose) protocols recommended by the National Institute of Clinical Excellence guidelines are widely implemented. Synthetic oxytocin is delivered as a continuous infusion with incremental rises in concentration every 30 min until adequate contractions are achieved (2–32 mU/min). In the United States and other countries, there is less uniformity in the protocols employed leading to concerns about the high concentrations used. With a half-life reported between 3 and 20 min, synthetic oxytocin use can be associated with uterine hyperstimulation, fetal distress, operative delivery and postpartum hemorrhage. Continuous exposure to oxytocin has also been reported to down-regulate the oxytocin receptors in myometrial muscle and in theory could predispose women to postpartum hemorrhage due to a refractory response to ergometrine/oxytocin treatments. As a result, the use of pulsatile rather than continuous infusion of synthetic oxytocin for induction and augmentation of labor has been proposed. The most recent randomized clinical trial (Tribe et al., 2012) reported that pulsatile oxytocin resulted in as many vaginal births as a continuous infusion with less uterine over-stimulation or reports of “suspected fetal distress.” The pulsatile infusion delivered 1/6th of the dose of oxytocin to achieve the same clinical outcomes which suggests current protocols could be modified. Given the potentially worrying side-effects of synthetic oxytocin, this could benefit women and provide a slower and more natural labor. In contrast, however, others argue that there is a need to introduce higher dose protocols to expedite labor and trials are ongoing.

The involvement of oxytocin in labor and delivery has also led to the hypothesis that inhibition of uterine oxytocin receptors can prevent preterm labor. Atosiban, a mixed oxytocin/vasopressin receptor antagonist has been introduced as a tocolytic in Europe as a first choice treatment for threatened preterm labor, although it failed to gain FDA approval for use in the United States.

Meta-analysis suggests that although atosiban has fewer side effects than other tocolytics, it is no better than placebo for important clinical outcomes such as gestation at delivery and neonatal wellbeing.

Other more selective oxytocin receptor antagonists have been developed. These include barusiban (for preterm labor, but not found to be effective), epelsiban (for treatment of premature ejaculation and to enhance myo/blastocyst implantation in IVF), L-368,899 (social behavior and pair bonding), L-371,257 (preterm labor, not yet tested) and retosiban (preterm labor, under investigation).

Alternative Clinical Uses for Oxytocin

The development of intranasal applicators has opened up the possibility of oxytocin being used in other conditions such as postpartum depression, autism, social dysfunction and anxiety, Parkinson's, schizophrenia, and sleep apnoea.

In general, intranasal administration appears to have few side effects and be safe to use in vulnerable as well as healthy individuals. In studies of postpartum depression, there have been very few significant findings compared to placebo. Some women have reported a sensation of "calmness" with oxytocin, but also negative effects such as rating baby-crying as more urgent and needing more harsh care-giving strategies have led to caution with implementing oxytocin as a treatment. With regard to social behaviors, there is ongoing debate as to whether oxytocin will provide a consistent panacea for all individuals (Leng and Ludwig, 2016). Continued research is needed that considers phenotype, optimal dosing and potential interactions with other neurotransmitters.

Pregnancy Complications (FGR, Preeclampsia)

Introduction

The development of the fetus within the maternal uterus is strongly determined by fetal genetic factors as well as factors derived from the mother and from the placenta as mediator between the two individuals. Using its intrinsic growth potential the fetus should be able to reach appropriate growth as a healthy fetus. However, only a fully functioning placenta in direct interaction with the mother can provide the respective nutritional and gaseous support of the fetus. This needs to be directly linked to the physiological adaptations of the maternal system during pregnancy. Any major alteration of this interactive interplay may result in pregnancy pathologies including fetal growth restriction (FGR) and preeclampsia.

Definitions and Features

Fetal Growth Restriction

Fetal or intra-uterine growth restriction (FGR/IUGR) remains one of the leading causes of perinatal mortality and morbidity of the baby, distressing nearly 5% of all pregnancies (Bernstein & Gabbe 1996). Perinatal mortality dramatically increases with reducing newborns' weight: A baby born with <2500 g of weight at term has a 5–30 times higher risk for perinatal mortality, while the risk for a baby born with <1500 g of weight is 70–100 times greater.

Although the terms FGR/IUGR and SGA (small-for-gestational age) are often used as synonyms, there is a clear difference between the two. By definition, both terms include newborns with a birth weight below the 10th percentile (Bernstein & Gabbe 1996). The term FGR includes babies that have not been able to fully utilize their genetic growth potential but due to various reasons ended up growth restricted. By contrast, the term SGA includes FGR babies as well as babies that have used their genetic potential but are genetically small and only reach a birth weight up to the 10th percentile. Thus, FGR is a subset of SGA rather than a synonym. Looking at the babies with a birth weight below the 10th percentile, all of these babies belong to the SGA group, while only about 30% of these newborns are growth restricted and hence belong to the FGR group.

Typical features of FGR in contrast to SGA are changes in blood flow of maternal and fetal blood vessels to the placenta, hence uterine and umbilical arteries, respectively (Cetin & Alvino 2009). Alterations of maternal blood flow towards the placenta can be visualized in the uterine arteries by looking at the presence of notches and an increased pulsatility index in Doppler ultrasound. These changes have been described being caused by insufficient invasion of extravillous trophoblast into spiral arteries. Thus, incomplete invasion of these vessels by endoarterial trophoblasts (Moser & Huppertz 2017) results in the fact that these vessels stay narrow and under maternal vasomotor control. Alterations of the fetal blood flow towards the placenta are other typical features of FGR and show an increased systole/diastole (S/D) ratio in the umbilical arteries. Variations of the theme include FGR cases with still preserved end diastolic flow (PEDF) in the umbilical arteries, absent end diastolic flow velocity in these arteries (AEDF) or even reversed end diastolic flow (REDF) (Sibley et al. 2002). One possibility to explain these changes is an increased peripheral resistance within placental vessels, maybe due to malformation of the placental villous trees or increased blood flow and pressure in the intervillous space (Burton et al. 2009).

Preeclampsia

Despite massive scientific and clinical efforts, the etiology of preeclampsia still remains obscure in a variety of aspects and thus preeclampsia stays as the pathology of hypotheses even today. It is generally accepted that the placenta rather than the fetus is the driver for the development of preeclampsia, while multiple other factors influencing the development of preeclampsia are under discussion.

Just as FGR, also preeclampsia belongs to the group of major reasons for maternal as well as fetal and neonatal morbidity and mortality. Worldwide, 2–8% of all pregnancies are affected by preeclampsia (ACOG 2013). This pregnancy specific syndrome induces long-term effects for mothers and children. As an example, women who experienced preeclampsia show a higher risk to develop cardiovascular diseases later in life (Bellamy et al. 2007).

The definition of preeclampsia includes diagnosis of hypertension and proteinuria in a so far normotensive woman (ACOG 2013). The diagnosis of hypertension is defined as developing systolic blood pressure of ≥ 140 mmHg, and/or diastolic blood pressure of ≥ 90 mmHg after 20 weeks of gestation, measured two times at least 4 h apart. Proteinuria is defined as ≥ 0.3 g protein in 24 h urine, or a protein to creatinine ratio of ≥ 3 (ACOG 2013). These two features are the typical criteria to define preeclampsia. However, especially in the absence of proteinuria other criteria may become important, including thrombocytopenia ($< 100,000$ platelets μL^{-1} blood), elevated levels (factor > 2) of liver transaminases in blood, elevated levels (> 1.1 mg/dL) of serum creatinine (indicating kidney insufficiency) as well as cerebral or visual disturbances or pulmonary edema (ACOG 2013).

The final clinical syndrome of preeclampsia is a maternal syndrome, while the baby in the womb may suffer as well from FGR or may show a completely normal development and growth. Hence, it is the combination of maternal response and susceptibility to factors derived from the placenta that defines time of onset, severity and progression of preeclampsia. Consequently, all three players, mother, fetus and placenta, including their interplay need to be considered when evaluating the etiology of preeclampsia.

Definition of preeclampsia subtypes

Due to the different times of onset and effects on mother and child, preeclampsia has been grouped into different subtypes. The two main types are early-onset preeclampsia with clinical symptoms forcing delivery before 34 weeks of gestation and mostly associated with a growth restricted baby and late-onset preeclampsia with delivery of the baby at or after 34 weeks of gestation and mostly associated with a normally grown baby. Looking at these two subtypes in more detail, further differences, other than time of delivery, can be identified:

1. Shallow invasion of extravillous trophoblast – mostly in the early-onset type;
2. Changes in perfusion of the placenta with maternal blood – mostly in the early-onset type;
3. Changes in the fetoplacental vasculature plus changes of fetal blood flow to essential organs – mostly in the early-onset type; and
4. Development of fetal growth restriction – mostly in the early-onset type.

Interestingly, the two subtypes do not differ in their features that directly define preeclampsia (hypertension and proteinuria) but rather differ in features related to fetal growth ([Huppertz 2008](#)).

The subtype of late-onset preeclampsia

Worldwide, the subtype of late-onset preeclampsia comprises >80% and up to 95% of all preeclampsia cases. In such cases delivery is preterm or at term (>34 weeks), while the babies and the placentas of such cases mostly show normal growth trajectories and are not growth restricted. The uterine arteries and thus maternal blood flow patterns towards the placenta are mostly normal as well. Doppler waveforms of the uterine arteries show no changes or a non-significant increase of the pulsatility index. In line with the normal growth rate of the baby are the non-altered blood flow parameters of the umbilical arteries from the fetus towards the placenta.

The above description shows that this subtype of preeclampsia is purely a maternal problem while the babies are mostly fine. The question remains whether a defect of the placenta needs to be involved in the etiology of this subtype or whether it is just the mother who responds inappropriately to a normally functioning placenta. It may be a combination of both as it has been shown that pregnant women with placentas that display enlarged mass and/or surface area (like in diabetes mellitus, multiple pregnancies, anemia, or high altitude) are at an increased risk to develop the late-onset subtype of preeclampsia.

The subtype of early-onset preeclampsia

Only a small proportion of 5–20% of all preeclampsia cases, depending on the statistics, belongs to the early-onset type of preeclampsia. This type of preeclampsia is responsible for the majority of preeclampsia-related fetal and maternal morbidity and mortality in the developed world ([Chappell et al. 2008](#)).

Different to the late onset type, most of the cases of the early-onset type show typical features in clinical routine. A feature that became a matter of particular interest was the change of blood flow within the maternal uterine arteries as described above for FGR. Another regular feature of the early onset cases is abnormal blood flow in the umbilical arteries, again as described above for FGR. Hence, clinically, this type of preeclampsia is characterized by a mixture of symptoms not directly related to preeclampsia. This, of course, has led to major speculations and interpretations over the last decades.

The Combination of Preeclampsia and FGR

The features listed above for early-onset preeclampsia in clinical routine are not specific for this type of preeclampsia. Interestingly, most early-onset preeclampsia cases are associated with FGR. Thus, the typical features of FGR (fetal growth restriction in combination with alterations of uterine and umbilical blood flow) are simply used to define early onset preeclampsia. This raises the question whether the clinically relevant features of early-onset preeclampsia cases (excluding hypertension and proteinuria) are caused by preeclampsia or are features that are due to the combined and overlying presence of FGR ([Huppertz 2008](#)). The combination of FGR and early-onset preeclampsia makes such cases so dangerous for mothers and babies and hence important for clinical intervention.

Disproof of the most Popular Hypothesis on the Etiology of Preeclampsia

Interestingly, a single hypothesis on the etiology of preeclampsia is present in literature since decades. This hypothesis is based on shallow invasion of extravillous trophoblast and subsequent failure of these cells to transform uterine spiral arteries into large bore conduits. It is of particular interest that this hypothesis is still present as it has been disproved by a number of publications already. Regardless of its disproval this hypothesis is still a major basis for scientific studies. This shows the importance of a critical view on hypotheses and that scientific falsification of a hypothesis does not stop its political use.

Since this hypothesis is still spread today, the reader can find a short summary of the chronology of events within this hypothesis below:

1. First trimester: A so far unknown deleterious effect on the extravillous trophoblast;
2. First and second trimester: Shallow invasion of extravillous trophoblasts with a clearly reduced infiltration of spiral arteries;
3. Second trimester: Reduced flow of maternal blood into the intervillous space of the placenta;
4. Second and third trimester: Placental hypoxia and/or waves of hypoxia followed by reoxygenation of the placenta;

5. Second and third trimester: Hypoxic damage of the villous trophoblast;
6. (Second and) third trimester: Release of placental factors from the syncytiotrophoblast (such as soluble Fms-like tyrosine kinase-1, sFlt-1, and placental growth factor, PlGF) into maternal blood;
7. (Second and) third trimester: Maternal inflammatory reactions due to the above placental factors and development of clinical symptoms of the mother.

This has been a conclusive hypothesis 10 years ago, while today a number of aspects have been disproved. Two aspects of this hypothesis will be further described below with a critical appraisal of their current scientific value.

Preeclampsia and Shallow Invasion of the Trophoblast

Of course, early-onset preeclampsia is clinically much more relevant than late-onset preeclampsia. Even if the symptoms of preeclampsia (hypertension, proteinuria) can be severe in both types, in late-onset cases immediate delivery is easy, while this may not be the case in early-onset cases with deliveries at <34 weeks of gestation. Additionally, fetal growth restriction mostly occurs in early-onset cases, putting another burden on the clinical management of these pregnant mothers. Hence, early-onset preeclampsia as the clinically more relevant type of preeclampsia has also attracted more scientific studies. And the clinically relevant features of early-onset preeclampsia including FGR have then been transferred to all preeclampsia cases.

However, as listed in **Definition of Preeclampsia Subtypes**, shallow invasion is a feature of early-onset rather than late-onset preeclampsia; hence it is present in <20% of all preeclampsia cases. Regardless, in literature this fact seems to be ignored as in nearly all studies shallow invasion is claimed as the main event for the etiology of preeclampsia in general. However, this may explain only <20% of all preeclampsia cases, while the remaining majority remains unexplained.

It is important to note that the cascade of events described for early-onset preeclampsia (1. shallow invasion of extravillous trophoblast; 2. reduced perfusion of the placenta with maternal blood; 3. fetal growth restriction) is exactly the cascade of events occurring in cases with pure fetal growth restriction without preeclampsia and without any clinical symptoms of the mother. Hence, it needs to be critically viewed whether shallow trophoblast invasion is really a feature of preeclampsia or just a coincidence in a specific subset of cases.

The idea of overlapping symptoms of two different syndromes is supported by studies using uterine artery Doppler to predict preeclampsia and/or FGR. In a study assessing uterine artery blood flow at 11+0 to 13+6 weeks by Doppler ultrasound the detection rate for early onset preeclampsia was only 40% at a 10% false positive rate (Nicolaidis et al. 2006). In another study assessing uterine artery Doppler at 11–14 weeks of gestation, the sensitivity to predict early-onset preeclampsia was 33.3%, while for all cases of preeclampsia (early and late-onset) the sensitivity decreased to 21%. However, using the same cohort of women, the sensitivity to detect early-onset FGR was 100% (Pilalis et al. 2007).

The above mentioned studies plus additional studies cast doubts on a direct and causal relationship between shallow trophoblast invasion and the etiology of preeclampsia. This dysregulation of the extravillous trophoblast seems to be directly related to idiopathic cases of fetal growth restriction. If this is true, then the above mentioned “specific” features of early-onset preeclampsia are simply due to FGR. This would further imply that there are no specific features of early-onset preeclampsia compared to late-onset preeclampsia – besides the earlier time point of delivery and the co-occurrence with FGR.

Preeclampsia, Reduced Placental Perfusion and Placental Hypoxia

During the first trimester of pregnancy the placenta is perfused by maternal plasma rather than maternal blood with blood cells. Hence, only physically solved oxygen is transported into the placenta, allowing oxygen concentrations of below 20 mmHg (Jauniaux et al. 2000). This oxygen concentration is normoxic for this organ and this period of pregnancy and should not be called hypoxia, which is pathologically low oxygenation of tissues and organs. Only with the start of blood flow into the placenta at the beginning of the second trimester the intra-placental oxygen concentration rises to values of about 60 mmHg (Jauniaux et al. 2000). If this increase in oxygenation starts too early, loss of placental mass or even spontaneous abortion may be the consequence (Jauniaux et al. 2003).

At the same time it needs to be considered that the tissues of the maternal uterus are normally perfused with arterial blood throughout pregnancy, hence with about 90 mmHg in arterial blood and about 40 mmHg in venous blood (Jauniaux et al. 2000). There is no or only very little changes of oxygenation of these tissues during pregnancy; hence, trophoblast invasion always takes place into well oxygenated uterine tissues (Huppertz et al. 2009). Thus, shallow invasion does not change oxygenation of the uterine placental bed but changes the way maternal blood flows into the intervillous space of the placenta.

After the steep increase in placental oxygenation at the beginning of the second trimester a slight decrease until term has been observed. The oxygen concentrations during the second and third trimester that have been measured are between 35 mm and 50 mmHg (Schaaps et al. 2005, Sibley et al. 2002, Kakogawa et al. 2010). Continuous oxygenation of the placenta is facilitated via widening and reorganization of the uterine spiral arteries that have been opened towards the intervillous space of the placenta by invading extravillous trophoblasts. It is important to note that the widening is mostly executed at the very placental end of the vessels leading to a funnel-shaped opening of the arteries towards the placenta.

At the same time the blood volume flowing into the placenta needs to be increased due to the growing needs of the fetus. Between week 20 and week 38 the uterine blood flow increases from about 450 mL min⁻¹ to nearly 1000 mL min⁻¹ (Konje et al. 2001).

What is the effect of the funnel-shaped transformation of the uterine spiral arteries?

Blood flow velocity through the uterine spiral arteries is relatively constant during the second half of pregnancy with values between 33 cm s^{-1} and 50 cm s^{-1} (Bahlmann et al. 2012). Burton et al. (2009) have used assumption on length and diameter of vessels, total blood volume and other measures to calculate the velocity of blood flowing into the placenta. The funnel-shaped opening of the vessels reduces the flow of maternal blood into the placenta to values of about 10 cm s^{-1} while it does not significantly change the total blood volume flowing into the placenta (Burton et al. 2009). This low velocity is essential to maintain the fragile construction of the villous trees, to allow distribution of blood through the narrow passages between the floating villi and to maintain the connection between anchoring villi and basal plate.

What is the effect of shallow trophoblast invasion?

Burton et al. (2009) have calculated that blood flow from opened but not widened spiral arteries into the placenta shows a velocity of $1\text{--}2 \text{ m s}^{-1}$ and thus is 10–20 times faster than in normal pregnancy. This has major deleterious effects on the placenta proper, which are not related to changes in oxygenation and oxygen concentrations. The increased blood flow velocity induces damages on the villous surface leading to increased deposition of fibrin-type fibrinoid, leads to detachment of anchoring villi from the basal plate and thus reduces the number of extravillous trophoblasts, and results in alterations of the whole villous tree arrangement. This in turn may well lead to reduced nutritional and gaseous support of the fetus and hence fetal growth restriction.

Does this lead to reduced placental perfusion and placental hypoxia?

Surprisingly, hundreds of publications use both, reduced placental perfusion and placental hypoxia, as basis for their studies. At the same time, up to now there is not a single measurement showing any data and proof for both events. Looking at placental oxygenation in preeclampsia and FGR, only a few data from indirect measurements have been published:

(1) The pO_2 in blood samples of the uterine veins prior to cesarean section has been used as a surrogate for the pO_2 in the placenta (Sibley et al. 2002). Based on the calculations of Schaaps et al. (2005) there is a fixed relation between the uterine vein pO_2 and the placental pO_2 , with the venous pO_2 being 1.5 times higher than the placental pO_2 . Respective measurements in blood from uterine veins yielded a mean value of 63 mmHg for FGR cases, significantly higher than the 50 mmHg in the control cases (delivery between week 24 and 36 of gestation for both groups). For the controls the placental pO_2 can be calculated to be 33 mmHg and for the FGR group 42 mmHg, 1.3-times higher than the pO_2 of the control cases (Sibley et al. 2002).

(2) Also measurements of the concentration of oxygenated hemoglobin (termed tissue oxygenation index; Kawamura et al. 2007, Kakogawa et al. 2010) have been used as surrogate for the placental tissue pO_2 . The tissue oxygenation index of the placenta was 71% in healthy pregnant women, 78% in cases with FGR and 80% in cases with early-onset preeclampsia and FGR (Kawamura et al. 2007, Kakogawa et al. 2010). The transfer of these values to placental pO_2 values results in 30 mmHg for normal pregnant women, 49 mmHg for FGR cases and 54 mmHg for cases with early-onset preeclampsia and FGR.

Taken together, all the above studies showed increased levels of the placental pO_2 in cases with preeclampsia and/or FGR. There is not a single publication showing measurements that proof placental hypoxia. Thus, the combination of the calculations on flow velocity and the surrogate measurements of the placental pO_2 provide information on increased oxygenation levels in cases with shallow trophoblast invasion. However, there is no basis for a hypothesis that uses with placental hypoxia as a major step in its reasoning.

New Explanations of the Etiology of Preeclampsia

As described above, the placenta is essential for the development of preeclampsia. At the same time, the placenta cannot be looked at on its own but needs to be put into a larger context with its environment. Only the interaction between placenta, release of placental factors and particles into the maternal circulation and finally the response of the mother on these factors determines whether the clinical symptoms of preeclampsia develop or not. Hence, each site and player needs to be taken into account to identify whether clinical symptoms become relevant (Huppertz, 2008).

Based on the close interactions between maternal and feto-placental factors during pregnancy, at least three different scenarios can be developed. These scenarios can explain the different timing, the different severities and the involvement of the fetus in preeclampsia and FGR as well as the long-term effects on mother and child.

Scenario 1: A Healthy Mother Meets a Placenta with a Dysfunctioning Villous Trophoblast - > Preeclampsia without FGR

During normal pregnancy, the syncytiotrophoblast releases factors via controlled secretion and apoptotic processes, the latter releasing syncytial knots into maternal blood (Huppertz et al. 1998, Huppertz 2008, 2010). In this scenario a dysfunctional syncytiotrophoblast additionally releases subcellular fragments due to necrotic and aponecrotic processes (Huppertz 2008, 2010). This results in disposal of subcellular micro- and nanoparticles (Johansen et al. 1999) that systemically activate the maternal endothelium and in the long run damage the maternal vascular system (Goswami et al. 2006). A malfunction of the placenta and especially of the syncytiotrophoblast results in a continuous release of factors damaging the maternal endothelium and finally leading to the clinical symptoms of preeclampsia. At the same time, the extravillous trophoblast is not affected and hence transformation of spiral arteries, perfusion of the placenta and growth of the fetus should be normal (Fig. 1).

Fig. 1 Sequence of events in cases with a healthy mother and a placenta with a dysfunctional villous trophoblast but normal extravillous trophoblast. This sequence most probably results in late-onset preeclampsia without FGR.

In this scenario, a pathological placenta with a dysfunctional syncytiotrophoblast releases particles and factors into maternal blood that not only activate but also harm the vasculature of the mother throughout pregnancy. The magnitude of damage can be directly related to placental surface area: The larger the surface area (e.g. in gestational diabetes, in multiple pregnancies or pregnancies at high altitude), the larger the amount of non-apoptotically released factors. On the maternal site the compensatory defense systems will be overloaded when the amount of placental factors reaches a specific threshold, resulting in an even faster damage of the endothelium.

If the defense systems of the mother can withstand the damaging effects of the placental particles for a longer time period, late-onset preeclampsia may develop. However, if the overload is too extreme, early decompensation may occur, leading to early-onset preeclampsia. In both scenarios the pathological changes of the placenta may not affect the nutritional and gaseous supply of the fetus too much, which leads to the delivery of a normally grown baby without growth restriction. Predictive markers of preeclampsia such as the angiogenic markers PlGF and sFlt-1 cannot predict such cases of preeclampsia as the maternal endothelium is affected only late in pregnancy. Furthermore, such markers may be more related to FGR than to preeclampsia (Nicolaidis et al. 2006, Pilalis et al. 2007). At the same time, markers specific for the syncytiotrophoblast such as placental protein 13 (PP13) could be used to identify these cases of preeclampsia, maybe already in the first trimester of pregnancy (Huppertz et al. 2008). This scenario may not lead to any harmful effects later in life for both, mother and child.

Scenario 2: A Healthy Mother Meets a Placenta with a Dysfunctional Extravillous Trophoblast - > FGR

If the placental defect is present in the extravillous rather than the villous trophoblast, the release of factors from the syncytiotrophoblast is unaffected and normal. In this scenario invasion of extravillous trophoblast is affected leading to inadequate transformation of uterine luminal structures (Fig. 2).

So far, only reduced infiltration of uterine spiral arteries has been documented. However, very recently it has been shown that extravillous trophoblasts invade into all luminal structures of the uterus. Uterine glands are the first structures that are invaded by endoglandular trophoblast; it already takes place during the first days of implantation (Moser et al. 2010, Moser & Huppertz 2017). Then invasion into uterine vessels occurs to allow flow of plasma to the placenta via invaded spiral arteries (endoarterial trophoblast) and draining of the plasma from the placenta back into the maternal vascular system by invaded uterine veins (endovenous trophoblast) (Moser et al. 2017, Windsperger et al. 2017). There is also invasion into the lymph vessels (endolymphatic trophoblast) of the placental bed, although its function is unclear so far (Windsperger et al. 2017).

The effect of insufficient invasion into glands and veins has not been studied so far. Insufficient invasion into glands by reduced endoglandular trophoblast invasion may well result in reduced histiotrophic nutrition of the embryo and thus growth restriction very early in pregnancy. Also, insufficient invasion into uterine veins by reduced endovenous trophoblast invasion may result in inadequate draining of the maternal plasma from the placenta early in pregnancy and also in inadequate draining of maternal blood later on pregnancy. Both will have deleterious effects on the flow of maternal blood through the placenta and hence supply of the embryo/fetus.

Coming back to spiral arteries where the effects of insufficient invasion by endoarterial trophoblasts has been widely studied. As outlined above, the results of inadequate invasion of spiral arteries is not reduced blood flow into the placenta and is not placental hypoxia. Rather, it is increased flow velocities of blood into the placenta leading to damage of the placental villous tree as well as increased peripheral resistance within the small and fragile placental vessels. This increased peripheral resistance may well result in alterations of perfusion of the placenta and thus to malnutrition of the fetus.

Fig. 2 Sequence of events in cases with a healthy mother and a placenta with a dysfunctioning extravillous trophoblast but normal villous trophoblast. This sequence most probably results in FGR without preeclampsia.

The changes in blood flow from the fetus to the placenta can be visualized by ultrasound of the umbilical arteries. Focusing on the flow pattern at the end of the diastole, mild form of FGR are associated with altered but still preserved flow at the end of diastole (preserved end diastolic flow, PEDF). In more severe cases, flow at the end of diastole may be absent (absent end diastolic flow, AEDF) or may even flow backwards (reversed end diastolic flow, REDF).

The combination in damage of the villous tree plus altered fetal perfusion of the placenta can easily lead to reduced nutritional supply of the fetus, which may result in a hypoxic fetus. Since the maternal oxygen supply into the placenta is mostly unchanged but less oxygen is transferred from the placenta to the fetus, the intraplacental oxygen level rises compared to normal pregnancy. The result is a hypoxic fetus with a hyperoxic placenta, as has been described in such cases (Sibley et al. 2002, Kawamura et al. 2007, Kakogawa et al. 2010).

This scenario may not lead to any harmful effects later in life for the mother; however, it may well induce long term effects on the child.

Scenario 3: A Predisposed Mother Meets a Normal Placenta - > Preeclampsia without FGR

In this scenario, the placental syncytiotrophoblast releases factors and particles in a normal way, that is via controlled secretion and apoptosis (Huppertz et al. 1998) (Fig. 3). This time, the mother shows a defect in her defense systems, which may include the endothelium, the whole vascular system, the scavenging systems or one or more specific signaling pathways to regulate blood pressure and/or kidney function. In such cases the mother may already be known to have predisposing diseases such as chronic hypertension or renal disease or may show subclinical alterations that have not been diagnosed before.

Depending on the extent of the maternal dysfunction, an overload of the scavenging systems or damage of the vascular system may occur early or late in pregnancy. The overload/damage is also dependent on the number of particles and factors released from the normal placenta. Hence, increased surface area of the placenta as present in multiple pregnancies or pregnancies at high altitude may foster the development of clinical symptoms.

The fetus should not be affected since the placenta shows normal growth trajectories; hence the baby should be delivered as a normally grown baby (no growth restriction). In this scenario, early changes of predictive markers like PlGF and sFlt-1 are mostly absent prior to onset of symptoms. Also placenta specific markers like PP13 may not enable early prediction of such cases as the placenta is normally developed.

In this scenario the women already suffer from clinical or subclinical defects of pathways affecting their vascular system. Hence, they are the ones with a high risk to develop cardiovascular diseases later in life, while the child should be unaffected.

Scenario 4: A Predisposed Mother Meets a Dysfunctioning Placenta - > Preeclampsia with or without FGR

This scenario includes the most severe cases since the combination of defects on both sites will result in deleterious effects for both, mother and child.

Scenario 4A: Placenta with dysfunctioning villous trophoblast

This subpopulation shows malfunction of the syncytiotrophoblast but not the extravillous trophoblast (Fig. 4). Hence, release of necrotic and aponecrotic particles and factors will take place with no alterations of blood flow towards the placenta. Since in these cases the maternal system is already defective, the systemic deterioration of the maternal system induced by the altered release from the syncytiotrophoblast will be fast. Hence, this subpopulation will result in cases with early-onset preeclampsia without fetal growth restriction. Due to the defect in the syncytiotrophoblast, predictive markers specific for the placenta, e.g. PP13, should easily predict such cases, while angiogenic markers such as PlGF and sFlt-1 may miss these cases.

Fig. 3 Sequence of events in cases with a predisposed mother and a normal placenta. This sequence most probably results in late-onset preeclampsia without FGR.

Fig. 4 4A: Sequence of events in cases with a predisposed mother and a placenta with a dysfunctioning villous trophoblast but normal extravillous trophoblast. This sequence most probably results in early-onset preeclampsia without FGR. 4B: Sequence of events in cases with a healthy mother and a placenta with a dysfunctioning villous trophoblast and a dysfunctioning extravillous trophoblast. This sequence most probably results in early-onset preeclampsia with FGR.

Scenario 4B: Placenta with dysfunctioning villous and extravillous trophoblast

This subpopulation shows malfunction of the syncytiotrophoblast as well as the extravillous trophoblast (Fig. 4). Hence, release of necrotic and aponecrotic particles and factors will take place with further alterations of blood flow towards the placenta. The damage due to the altered perfusion of the placenta may further enhance the damage of the syncytiotrophoblast and hence increase the release of particles from the placenta (Huppertz 2011). In combination with the already present damage of the maternal defense system, the damage of the maternal vascular system will develop early (early-onset preeclampsia), while the fetus will suffer from impaired growth as well (fetal growth restriction). Such cases can be predicted by placenta specific (Chafetz et al. 2007) as well as angiogenic markers (Schaarschmidt et al. 2013).

In this scenario, women in both subpopulations are predisposed and will most probably suffer from developing high risk for cardiovascular and other diseases later in life. In the second subpopulation with FGR, also the children show fetal programming and an increased risk to develop morbidities later in life (Longtine & Nelson 2011).

Conclusions

The etiologies of preeclampsia and FGR are still obscure and need further fruitful experiments and discussion. The list of new explanations clearly displays that the origin of both syndromes has not been identified yet. New routes of trophoblast invasion have been identified opening the way to new perspectives in thinking of new hypotheses. It has become obvious that the close

interplay between mother, placenta and fetus needs more attention as looking at only one site cannot explain the whole interactive setting.

Introduction

The success of pregnancy (i.e., birth of a healthy baby to a healthy mother) depends on multiple biological events and processes including: (1) appropriate interaction at the fetal/maternal interface to alter maternal physiology such that the allogenic embryo can implant to establish pregnancy and is not rejected by the maternal immune system; (2) a specific and ordered sequence of events in the embryo/fetal development program; (3) the nutritional, metabolic, and physical needs of the conceptus are satisfied as pregnancy advances; and (4) the appropriate timing and process of parturition so that birth occurs when the fetus is sufficiently mature to survive outside the uterus. This article addresses the process and timing of parturition and how this critical event in the reproductive cycle of viviparous species is controlled.

The Process of Parturition

The process of parturition involves: (1) transformation of the myometrium (smooth muscle of the uterine wall) from a quiescent and relaxed state to a highly contractile and excitable state, wherein it contracts forcefully and rhythmically to produce the contractions of labor and become the engine for birth; (2) remodeling of the extracellular matrix (ECM) in the uterine cervix such it transforms from a closed, rigid and unyielding structure, to a softened structure that distends in response to increased intrauterine pressure to open the uterine outlet (gateway for birth) allowing the conceptus (fetus and placenta) to be moved by uterine contractions into the vaginal canal; and (3) weakening and rupture of the fetal membranes (amnion and chorion) to release the fetus from the amniotic sack. These events are usually coordinated and occur at a time in pregnancy referred to as term, when fetal maturation is sufficient for it to survive as a neonate, and maternal physical, metabolic and behavioral processes are conducive to the parturition process and nurturing the neonate. Human term is between week 37 and 40 of gestation.

The Myometrium

For most of pregnancy the myometrium is relaxed, quiescent and compliant, and grows mainly by stretch-induced cellular hypertrophy of myometrial cells to accommodate the growing conceptus. The initial phase of parturition involves a phenotypic transformation whereby myometrial cells gain the capacity to contract forcibly, rhythmically and coordinately, and become more responsive to uterotonic hormones (factors that directly induce uterine contraction) such as oxytocin (OT) and prostaglandin- $F_{2\alpha}$ (PGF $_{2\alpha}$). This transformation involves increased expression of a specific cohort of genes encoding factors collectively referred to as contraction-associated proteins (CAPs). Some important CAPs include connexin-43 (CX43) that forms gap-junctions between myometrial cells, allowing rapid electrical, and chemical signaling between adjacent cells to permit synchronous contractions, receptors for stimulatory uterotonins (e.g., OT and PGF $_{2\alpha}$ receptors) leading to increased responsiveness to hormones that stimulate uterine contraction, and ion channels that decrease the resting membrane potential to increase excitability by lowering the threshold for contraction.

The Cervix

Although myometrial contractions move the fetus into the lower uterine segment, birth cannot occur unless the uterine cervix—a cylindrical extension of lower uterine segment that has a central canal connecting the uterus with the upper end of the vagina—dilates. For most of pregnancy the cylindrical wall of the cervix is composed of a dense and rigid fibrous ECM, which is unyielding and maintains a narrow canal that resists tensile forces generated by myometrial contractions and increased intrauterine pressure. In the nonpregnant state the cervical canal, albeit narrow, is open to allow menstrual discharge and entry of sperm. However, during pregnancy the canal is occluded by a mucous plug that separates the uterine and vaginal cavities. The mucous plug is usually discharged late pregnancy when the cervical canal dilates.

Parturition involves remodeling of the cervical wall ECM such that it softens and dilates in response to upward circumferential force from myometrial contractions, increased intrauterine pressure and the force of gravity. Changes in the biomechanical properties of the cervix begin before the onset of active labor and can be divided into three stages: softening, ripening, and dilation. Softening of the cervix occurs by restructuring of the collagen architecture, and increases progressively after mid-gestation, causing gradual thinning of the cervical wall and shortening of the cervical canal (i.e., distance between the uterine and vaginal openings). Although the tensile strength of the cervix is maintained during the softening phase, the rate of softening and cervical length decrease, which can be monitored by ultrasonography, may affect the timing of parturition since cervical shortening at mid gestation is a strong predictor of preterm birth. In contrast, cervical dilation occurs at parturition and within hours during active labor. This dramatic biomechanical change significantly decreases the capacity of the cervix to resist tensile force, and consequently the cervical canal dilates in response to the contractions of labor and simultaneous downward pressure from the fetus (usually the fetal

head). Eventually the dilation becomes sufficient to allow myometrial contractions to force the conceptus into the vaginal canal and subsequent birth. After birth the cervix remodels to reestablishes the rigid ECM architecture and narrow canal.

Fetal Membranes and Decidua

Human parturition requires rupture of the fetal membranes. The fetal membranes comprise the amnion membrane and the adjacent chorion and maternal decidua (the endometrium of pregnancy). In most women experiencing parturition at term, membrane rupture follows the initiation of myometrial contractions. However, in some women (~10%) fetal membrane rupture occurs without contractions and sometimes preterm. Interestingly, approximately 30% of women experiencing preterm parturition have preterm premature rupture of membranes without myometrial contractions suggesting a fetal membrane/decidua component in the etiology and pathophysiology of preterm parturition.

At parturition fetal membranes adjacent to the cervix separates from the decidua, which leads to the release of fetal fibronectin, which is normally located in the chorion–decidual contact zone. In this context, fetal fibronectin in the cervical-vaginal fluid serves as a biomarker for term and preterm parturition. In addition a mechanically weak zone develops in the membranes overlying the cervix which eventually becomes the site of membrane rupture. The weakening is associated with inflammation and inflammatory cytokines at the chorion–decidua interface, and may be a mechanism by which inflammation in the cervix induces rupture of the adjacent fetal membrane.

Thus, the process of parturition involves activation of the uterine musculature to produce the forceful contractions of labor, remodeling of ECM in the cervix to open the gateway for birth, and weakening of the fetal membranes to release the fetus from the amniotic sack. A key to unraveling the physiology and timing of parturition is to understand how these processes are controlled.

The Hormonal Control of Parturition

Specific biomechanical changes in each of the uterine compartments (myometrium, cervix, and amnion–chorion–decidua) are controlled by a complex interplay of hormonal (especially the steroid hormones progesterone and estradiol) interactions between the maternal and fetal tissues. The process of parturition is an inflammatory event that involves marked tissue-level inflammation within the myometrium, cervix, and decidua, characterized by activation of resident and infiltrating immune cells (e.g., macrophages, neutrophils, dendritic cells) and increased local levels of pro-inflammatory cytokines, including $\text{PGF}_{2\alpha}$ and chemokines (e.g., interleukin-8) that further stimulate inflammation to produce a tissue-level positive-feedback inflammatory state. For most of pregnancy the balance of regulatory signals favors inhibition of inflammation, myometrial quiescence, cervical closure, and the mechanical integrity of the fetal membranes. Parturition is induced by a switch in the balance to favor tissue-level inflammation and the production of uterotonic hormone that promote myometrial contraction and cervical softening and effacement and membrane weakening.

Hormonal Control of the Gravid Uterus

Growth and function—especially contractility and vascularity—of the gravid uterus are primarily controlled by the uterotrophic steroid hormones progesterone and estrogen (mainly estradiol). With respect to parturition these hormones affect myometrial contractility, the biomechanical integrity of the uterine cervix, and the inflammatory state of the decidua.

As its name implies, progesterone is a pro-gestation hormone; it is essential for the establishment and maintenance of pregnancy. For most of pregnancy progesterone blocks parturition by promoting myometrial relaxation and cervical rigidity and closure, and decreasing uterine cell responsiveness to pro-inflammatory/pro-labor stimuli. In contrast, it is generally considered that estrogen opposes progesterone by stimulating biochemical and physical changes in the myometrium, cervix, and fetal membranes that favors labor. During most of pregnancy labor-blocking and antiinflammatory actions of progesterone dominate. Parturition is induced when the actions of progesterone are withdrawn, which permits increased influence of estrogen and other pro-labor/pro-inflammatory hormones to induce parturition.

The hormonal control of parturition also involves uterotonic hormones that directly induce or repress myometrial contraction. The most notable are PGs (mainly $\text{PGF}_{2\alpha}$) and OT that directly stimulate myometrial contraction. PGs also promote cervical ripening. PG synthesis by the amnion, chorion, decidua, and myometrium increases during the prelude to, and in association with, the onset of labor. The increase in PGs is also due to increased synthesis by resident and infiltrating leukocytes into the myometrium, cervix, and decidua as part of the tissue-level inflammation that occurs during parturition. The central role of PGs in the control of parturition is reflected by clinical studies showing that administration of PGE_2 or $\text{PGF}_{2\alpha}$ to women at any stage of pregnancy induces labor by stimulating myometrial contractions and cervical ripening, and that inhibition of PG biosynthesis with aspirin, indomethacin, or specific PG synthase inhibitors suppresses labor and prolongs gestation.

OT, a 9-amino acid peptide secreted by the posterior pituitary, is a potent stimulator of uterine contraction and is routinely administered to augment the contractions of labor and treat postpartum hemorrhage. Vaginal distention is a principal stimulus for the release of pituitary OT via a neurologic feedback mechanism known as the Ferguson reflex. Thus, during the latter stages of parturition a positive feedback neuroendocrine interaction occurs whereby distention of the vaginal canal induced release of OT from the posterior pituitary which promotes myometrial contraction leading to further vaginal distention. As OT in the maternal

circulation does not increase prior to the latter stages of active labor, it is not generally considered to be involved in the initiation of parturition, but instead is thought to be a key stimulatory uterotonic required for the progression and completion of labor and delivery. OT effects on myometrial cells are mediated by the OT receptor (OXTR), whose abundance in myometrium increases gradually toward the end of pregnancy and rises significantly in association with the onset of labor. Expression of the OXTR by myometrial cells is inhibited by progesterone and increased by estrogen. Thus, induction of OT responsiveness by increased OXTR expression may be the principal mechanism underlying the uterotonic actions of pituitary OT in the pregnancy uterus. After birth, pituitary OT promotes lactation and stimulates the tonic contraction of the myometrium needed for postpartum uterine hemostasis.

The Progesterone Withdrawal Trigger for Parturition

A common characteristic among viviparous species is that progesterone is essential for pregnancy maintenance and its withdrawal is a key trigger for parturition. In most species parturition at term is initiated by a prepartum decrease in circulating progesterone levels (referred to as systemic progesterone withdrawal), and in all species interventions that disrupt progesterone synthesis or action induce parturition at all stages of pregnancy. Thus, progesterone blocks parturition and removal of the progesterone block alone is sufficient to initiate the full cascade leading to delivery. The mechanism and control of progesterone withdrawal is therefore central to the hormonal control of parturition.

In most species parturition is triggered by a systemic progesterone withdrawal. For example, in mice progesterone is supplied by the maternal corpus luteum (CL) and the progesterone withdrawal trigger for parturition is caused by hormonal signals from the uterus that induce luteolysis. In sheep progesterone is produced by the placenta and parturition is caused by hormonal signals from the fetus, mainly in the form of cortisol, that decreases placental progesterone secretion. In women parturition is induced at any stage of pregnancy by disruption of progesterone activity [e.g., by administration of RU486, a progesterone receptor (PR) antagonist]. However, human parturition at term or preterm is not associated with decrease in systemic progesterone. Instead, circulating levels of progesterone (and estrogens) are high for most of human pregnancy and during labor and delivery. Despite persistently elevated levels of progesterone throughout pregnancy, prophylactic progestin supplementation is used as a therapy to prevent preterm birth. The effectiveness of this treatment, however, is controversial since any benefits are detected only in a relatively small subset of women with an elevated risk for preterm birth due to a previous preterm birth or a short cervix. Thus, a deficiency in progesterone is not likely to be the underlying cause for preterm birth and decreased progesterone availability to cell targets in the uterus is not a mechanism for normal term parturition. To explain this conundrum, it is hypothesized that human parturition is triggered by a functional progesterone withdrawal, whereby uterine cells become refractory to progesterone actions. One mechanism by which this occurs is via changes in progesterone receptor (PR) signaling in uterine cells ([Mesiano et al., 2002](#)).

The capacity for progesterone to sustain pregnancy and block parturition is dependent on the expression and activity of the nuclear PRs in uterine cells where they function as ligand-activated nuclear transcription factors. The human PR exists as two major isoforms: the full length PR-B, and the truncated (by 164 N-terminal amino acids) PR-A. Responsiveness to progesterone is dependent on the combined actions of PR-A and PR-B. Studies in term myometrium and myometrial cell lines suggest that functional progesterone withdrawal is caused by differential activity of the PR isoforms such that pro-gestational actions of progesterone are mediated by PR-B and this effect is inhibited by repressive actions of PR-A that decreases the transcriptional activity of PR-B ([Mesiano et al., 2002](#)). Other mechanisms for functional progesterone withdrawal include increased expression of PR-B co-repressors ([Condon et al., 2003](#)), inhibition of PR activity by other transcription factors ([Kalkhoven et al., 1996](#)), and reduced binding of PRs to DNA ([Nadeem et al., 2016](#)). Progesterone also may become inactivated in uterine cells before it interacts with the PRs by its metabolism to an inactive form causing the PRs to become unliganded and therefore inactive ([Nadeem et al., 2016](#)). Data also suggest that PR signaling in myometrial cells is modulated by specific micro RNAs ([Williams et al., 2012](#)). Thus, human parturition may involve multiple redundant processes to cause PR-mediated functional progesterone withdrawal and local inactivation of progesterone ([Fig. 1](#)). The hormonal interactions that control progesterone withdrawal, whether it be functional, systemic or local, are key regulatory factors in the hormonal control of parturition.

Inflammatory Triggers for Parturition

It is now clear that parturition is an inflammatory process and that it can be triggered by inflammatory stressors leading to tissue-level inflammation in the myometrium, cervix, and decidua. This implies that inflammation is upstream of progesterone withdrawal in the hormonal control of parturition. Implicit in the hypothesis that labor is induced by inflammation is the notion that pregnancy is maintained if inflammation is inhibited. Progesterone acting via the PRs exerts antiinflammatory actions in uterine cells and decreases responsiveness to pro-inflammatory/pro-labor stimuli suggesting that progesterone sustains pregnancy by blocking inflammatory triggers for parturition ([Amini et al., 2016](#); [Tan et al., 2012](#); [Hardy et al., 2006](#)). In myometrial cells anti-inflammatory effects of progesterone are mediated mainly by PR-B and antiinflammatory effects of PR-B are inhibited by PR-A consistent with PR-A-mediated functional progesterone withdrawal. Interestingly, the capacity for PR-A to inhibit the antiinflammatory activity of PR-B in myometrial cells is induced by pro-inflammatory stimuli ([Amini et al., 2016](#); [Peters et al., 2017](#)). This effect is consistent with the concept that inflammation is upstream of functional progesterone withdrawal in the trigger mechanism for human parturition.

Fig. 1 Possible mechanisms for progesterone withdrawal in human parturition. Actions of progesterone could be eliminated to trigger parturition by: (1) metabolism of progesterone (P4) to an inactive form (e.g., 20α -dihydroprogesterone; 20α -DHP); (2) isoform switching and activation of PR-A transrepression of PR-B; (3) interaction of PRs with other transcriptional regulators that block PR-B activity at specific gene promoters; and (4) uncoupling of progesterone from the PR.

Fig. 2 Model to explain the functional interaction between pro-labor inflammatory stressors and PR-A-mediated functional progesterone withdrawal in the induction of human parturition. The net effect of multiple pro-labor signals places an inflammatory load on the gravid uterus that gradually increases with advancing gestation. For most of pregnancy response of uterine cells to inflammatory load is controlled (mainly surpassed) by progesterone via PR-B. An inflammatory load threshold exists above which the trans-repressive activity of PR-A is induced which inhibits the anti-inflammatory action of progesterone mediated by PR-B. This causes tissue-level inflammation in the uterine compartments that increases local PG levels that transform the uterus to the labor state.

The functional interaction between inflammation and progesterone/PR signaling suggest a model for the hormonal control of parturition (Fig. 2). It is expected that the uterus is exposed to multiple pro-inflammatory/pro-labor stimuli throughout pregnancy. Some are intrinsic to the normal maternal/fetal physiology of pregnancy (e.g., uterine distention, fetal maturation, placental senescence, maternal metabolic stress), while others are extrinsic (e.g., intrauterine infection, maternal environmental stress). The stressors impart on the pregnancy uterus a net inflammatory load that increases with advancing gestation. It is proposed that an inflammatory load threshold exists, which when surpassed, triggers parturition via PR-mediated functional progesterone withdrawal. Decreased antiinflammatory actions of progesterone could then create a positive-feedback inflammatory state within the uterine tissues leading to local production of PGs that promote labor. The increased incidence of preterm birth associated with infection/inflammation and fetal/maternal stress supports this concept. The paradigm predicts that altering the inflammatory load trajectory and/or functional progesterone withdrawal threshold may be effective strategies to prevent preterm birth.

Estrogen Stimulation of Parturition

Estrogens (mainly estradiol) have the opposite effects of progesterone on the gravid uterus by promoting its transition from quiescence to labor. Mechanisms by which estrogen promotes parturition include: (1) increasing responsiveness of myometrial cells to OT and PGs by increasing cognate receptor levels; (2) promoting synchronization of contractions by increasing expression of CX43 that leads to formation of functional gap junctions between myometrial cells, and (3) increasing expression of proteolytic enzymes by cervical fibroblasts and decidual cells to promote cervical ripening and membrane rupture, respectively. In most species pro-labor estrogenic actions are induced by increased estradiol levels during the prelude to labor and in conjunction with systemic

progesterone withdrawal. This does not occur on women. Instead, the estrogen milieu of human pregnancy is high throughout pregnancy and persists during labor and delivery. The reason for this is that the human placenta produces estrogens (estradiol, estrone, estriol, and estetrol) throughout pregnancy. The high circulating estrogen levels suggest that the uterine tissues are refractory to pro-labor estrogenic actions for most of pregnancy, and that parturition involves increased responsiveness of uterine cells to estrogens (i.e., estrogen activation). Increased estrogen responsiveness at parturition appears to be coordinated with functional progesterone withdrawal via a reciprocal interaction between progesterone/PR signaling and estrogen/ER signaling. In general, progesterone decreases estrogen responsiveness by decreasing ER expression and estrogen increases progesterone responsiveness by increasing PR expression. Thus, human parturition may involve a functional estrogen activation that is coordinated with, and possibly secondary to, functional progesterone withdrawal. In this context, interaction between the ER and PR systems in uterine cells and the regulation of this process by pro-labor/pro-inflammatory stimuli may be of paramount importance for the control of human parturition.

The Timing of Parturition

Parturition before term increases mortality and morbidity risk for the neonate due to insufficient in utero development and functional immaturity of organ systems needed to survive outside of the uterus and independent of the placenta. Parturition after term increases mortality and morbidity risk for the mother and neonate due to fetal overgrowth and the associated problems with labor and delivery. In this context the hormonal control of parturition is expected to involve signals linking birth timing with fetal maturation such that birth occurs only after the fetus is prepared for extrauterine life and before it becomes too large to pass through the birth canal. This hormonal signaling is apparent in the sheep in which parturition is induced by increased activity of the fetal hypothalamic–pituitary–adrenal (HPA) axis that produces a surge of cortisol during the week before parturition (Liggins, 1994). Cortisol increases the metabolism of progesterone to estradiol in the sheep placenta leading to a systemic decrease in maternal progesterone and a concomitant increase in estradiol that induces changes in the uterine tissue to initiate parturition. Importantly, cortisol from the fetal HPA axis also promotes the functional maturation of fetal organ systems, especially the lungs, that the neonate will need after birth. Thus, in sheep the timing of parturition is linked to fetal maturation via activity of the fetal HPA axis. The effect of cortisol on the maturation of organ systems in fetus appears to be conserved in multiple species including humans (Young et al., 2010). Glucocorticoid promotion of fetal lung maturation is especially important because the inability to exchange gases due to pulmonary immaturity (i.e., respiratory distress syndrome due to lack of surfactant) is the leading cause of neonatal morbidity and mortality among preterm infants. This is the underlying rationale for the practice of glucocorticoid therapy (usually with synthetic glucocorticoids that cross the placenta) to women presenting with preterm labor in an effort to stimulate fetal organ maturation (especially surfactant production by the lungs) to increase neonatal competency if preterm birth occurs. However, unlike the sheep, cortisol production by the fetal HPA is not involved in the timing of human parturition.

In most species parturition is induced by maternal stressors which represents a mechanism by which the mother terminates pregnancy as a survival response. Normal term birth is preceded by increased inflammation in the myometrium, decidua and cervix and preterm birth is commonly associated with intrauterine infection, clinically silent upper genital tract infection, and bacterial vaginosis. This suggests that maternal stress, at least in the form of inflammatory stimuli impacting the uterine tissues, is a trigger for parturition and is consistent with the inflammatory load hypothesis (Fig. 2). The concept is supported by animal studies showing that administration of pro-inflammatory cytokines or factors that induce a pro-inflammatory response, initiate parturition.

The timing of parturition can also be considered from an evolutionary perspective. Natural selection favors traits that increase reproductive efficiency. In viviparous species this affects pregnancy and parturition to optimize factors such as maternal habitus, fetal size, litter size, uterine shape, and nutrient access. The timing of parturition could decrease reproductive efficiency if the fetus is born too early, which would compromise neonatal survival, and if it is born too late, which would compromise maternal and fetal survival if the fetus is too large to pass through the pelvic outlet. The former causes loss of a pregnancy, while the latter causes loss of a female's future pregnancies. It is reasonable, therefore, that natural selection favored a combination of maternal and fetal triggers for parturition. This effect is reflected in the diversity and specificity of parturition timing across viviparous species. In general, the mechanism by which parturition is controlled and timed in a particular species is suited to its overall reproductive strategy and selected through evolution to optimize reproductive efficiency. Consequently, the timing of birth relative to fetal/neonatal maturation varies greatly. Some species (e.g., marsupial, rodent) give birth to highly altricial neonates that are helpless and require considerable nurturing, while others (e.g., ovine, bovine, some primates) give birth to precocial neonates that can run with the herd soon after birth. In general primates give birth to precocial neonates. The human neonate, however, although being a primate, is born highly altricial. One explanation for this is that the timing of hominid birth was altered by natural selection to favor encephalization that caused a marked increase in brain size especially during fetal development. The fossil record shows that hominid brain size began increasing around 1 million years ago and has remained constant for at least the last 100,000 years. This was likely associated with increase brain and head growth during fetal development that eventually would lead to cephalo-pelvic disproportion at birth. Thus, the advantages of encephalization would have been balanced by the costs of neonatal and maternal loss due to difficulties at birth. Consequently, human pregnancy has significantly less obstetric capacity–space between the infant head and maternal pelvis–compared to other extant primates (Rosenberg and Trevathan, 2001, 2002). To solve the problem of cephalo-pelvic disproportion at birth, hominid evolution is thought to have favored traits that shortened pregnancy length so that the fetus is born before its head becomes larger than the obstetric capacity. A consequence of this selection would

be that the human neonate is less mature at birth than other primates; which indeed is the case. However, as natural selection operates at the population level over multiple generations rather than the individual, the mechanism for human birth timing, although not be ideal, is sufficient to provide an overall advantage. This is reflected by the relatively high incidence of pregnancy failure (compared with other species) and the general difficulty of human parturition due mainly to the large fetal head. Thus, the evolutionary biology of parturition highlights the variability in the physiologic mechanisms that control the parturition process and its timing. Although certain traits, such as progesterone withdrawal and inflammation as triggers for parturition appear to be conserved across viviparous species, differences in the mechanism and relative importance of those processes explain much of the comparative biology of parturition.

Glossary

AGD Ano-genital distance is the length of the space between the caudal aspect of the genital tubercle (penis in males) and the anterior aspect of the anus.

5 α -DHT 5 α -dihydrotestosterone.

EDCs Endocrine disrupting chemicals.

E₂ Estradiol.

IUP Position in the uterus of a fetus relative to siblings of the same or opposite sex.

T Testosterone.

Background

The focus of this article will be on the effects of very small differences in the sex steroids estradiol and testosterone on male and female fetal development due to a random developmental event, namely, whether embryos implant adjacent to male or female fetuses when there are multiple embryos in a uterus, which I referred to as the intrauterine position phenomenon (IUP) (vom Saal, 1981). This phenomenon results from the diffusion of sex hormones across the amniotic and chorionic placental membranes via amniotic fluid into the blood of adjacent fetuses (Fig. 1). To produce animals from known intrauterine positions, females are time mated, and just prior to parturition, pups are Cesarean delivered. Fetal location in the uterus is recorded, animals are individually marked for subsequent identification and raised by foster mothers for examination of phenotypic consequences during postnatal life.

The intrauterine position phenomenon has revealed the exquisite sensitivity of mammalian fetuses to very small perturbations in sex hormones, with significant consequences for subsequent life history (reviewed in vom Saal, 1981, 1989; vom Saal et al., 1999; vom Saal, 2016). This phenomenon provides the only mammalian model for relating postnatal traits to concentrations of endogenous hormones to which individuals are exposed at variable levels during the fetal period of sexual differentiation. Results from studies using this naturally occurring model system in litter-bearing species have provided insights concerning the consequences of individual differences in steroid concentrations during sexual differentiation that likely apply to all mammals, as revealed by significant effects of IUP identified in studies of human twins. In general, when there is a sex difference in a trait, a female fetus positioned next to males in utero has traits that are significantly more masculinized relative to female siblings that are next to only other female fetuses in utero. The effects on males of being adjacent to male or female fetuses is more complicated due to the fact that both testosterone and estradiol regulate specific aspects of masculinization (vom Saal, 2016).

Sexual differentiation in female mammals is less well understood than in males in terms of hormonal influences, although research has shown that exposure to testosterone and estrogenic hormones, drugs and environmental chemicals during development can lead to significant changes in organ function and disease in females as well as males. Importantly, fetal sexual differentiation is not just regulated by testosterone, although it is clearly the primary factor in masculinization, and for some aspects of sexual differentiation in males and females estradiol, other hormones (Gupta and Goldman, 1986; Zambrano et al., 2014), and environmental factors (Gore et al., 2015) have significant effects.

In mammals, sexual differentiation in males begins shortly after the onset of differentiation of the embryonic gonads into testes, after which testosterone secreted by Leydig cells initiates the process of masculinization. Sexual differentiation occurs primarily during prenatal life in mammals with a long gestation, as opposed to short-gestation species such as mice and rats where this process spans both prenatal and neonatal life. Thus, the impact of IUP on specific aspects of sexual differentiation (masculinization vs. defeminization) and other physiological processes varies between species. Specifically, sexual differentiation in mice and rats begins during the last few days of fetal life and continues into the early neonatal period (vom Saal, 2016). Due to the fact that sexual differentiation begins during the first trimester of pregnancy in humans, there is currently no method for assessing the levels of hormones in the blood of a human fetus during sexual differentiation, thus precluding examining the consequences of variability in gonadal steroid levels during fetal life for postnatal traits. Available evidence indicates that levels of compounds in amniotic fluid and blood are not the same (vom Saal et al., 2014), and thus amniotic fluid levels of hormones (determined by amniocentesis) cannot accurately identify the bioactive concentration of hormones in blood.

Differences in phenotype due to IUP were initially attributed only to differences in serum testosterone, thus, male and female fetuses positioned between female fetuses in early publications were referred to as 0M males (not next to a male fetus) rather than 2F males. However, findings concerning the effects of IUP on the male reproductive system led to experimental studies identifying that IUP effects were mediated by differences in serum estradiol as well as testosterone. Given the very small differences in free serum

Fig. 1 Total serum concentrations of testosterone (T) and estradiol (E₂) on gestation day 18 (1 day prior to parturition) are shown for male and female CF-1 mouse fetuses from different intrauterine positions. Since only 0.22% of estradiol is not bound to plasma proteins (both albumin, with high capacity but low affinity, and high-affinity alphafetoprotein produced by the fetal liver) on gestation day 18 (vom Saal et al., 1997), the difference in free serum estradiol concentration between 2M and 2F female fetuses is calculated to be 0.09 pg mL⁻¹ (corresponding to a 40 pg mL⁻¹ difference in total serum estradiol). The difference in free serum estradiol concentration between 2M and 2F mouse males is 0.05 pg mL⁻¹, corresponding to a 23 pg mL⁻¹ difference in total serum estradiol. There are no high affinity testosterone binding proteins in fetal rat or mouse serum, and the fraction of serum testosterone not bound to albumin is free (vom Saal et al., 1992). Arrows in the arteries and veins indicate the direction of blood flow. Based on data in vom Saal, F. S. (1989). Sexual differentiation in litter-bearing mammals: Influence of sex of adjacent fetuses in utero. *Journal of Animal Science* **67**, 1824–1840; vom Saal, F. S. and Dhar, M. G. (1992). Blood flow in the uterine loop artery and loop vein is bidirectional in the mouse: Implications for transport of steroids between fetuses. *Physiology and Behavior* **52**, 163–171; Even, M. D., Dhar, M. G. and vom Saal, F. S. (1992). Transport of steroids between fetuses via amniotic fluid in relation to the intrauterine position phenomenon in rats. *Journal of Reproduction and Fertility* **96**, 709–716.

estradiol between 2M and 2F fetuses of the same sex, it is easy to understand that there was skepticism 40 years ago concerning the hypothesis that these small differences in serum estradiol might account for some of the significant differences in phenotype related to IUP.

Testosterone can act directly in some target tissues or it can serve as a pro-hormone and act in other tissues after conversion to the more potent androgen 5 α -dihydrotestosterone (5 α -DHT) by the enzyme 5 α -reductase, or after conversion to estradiol by the enzyme aromatase. Gonadal steroids permanently influence 5 α -reductase (Type 2) and aromatase activity during differentiation of accessory reproductive organs (different isoforms of 5 α -reductase are in other tissues). In addition, estradiol regulates the expression of androgen receptors in the developing prostatic region of the urogenital sinus, but not in the organs that form from the Wolffian ducts (Taylor et al., 2011; vom Saal, 2016).

During critical periods in fetal life hormonal signals (endocrine and paracrine) regulate the differentiation of cells and thus the future functioning of organ systems. These hormonal signals operate at very low concentrations and low receptor occupancy. The endocrine system evolved to be responsive to very small changes in free serum hormone concentrations and to operate in a portion of the receptor binding range of hormone concentration that is nearly linear between hormone concentration and receptor occupancy, which is below 10% occupancy of total receptors (Welshons et al., 2003). An important point is that for lipophilic sex hormones, it is the free concentration in blood that determines bioactivity (Nagel et al., 1999).

An unexpected consequence of findings concerning the intrauterine position phenomenon was that they led to the prediction, now confirmed, that exposure during development to chemicals in the environment that interfere with hormones, such as testosterone and estradiol, known as endocrine disrupting chemicals (EDCs), might result in subsequent adverse health effects at much lower levels of exposure than were being examined by toxicologists conducting regulatory guideline studies for use in risk assessments (Colborn et al., 1996; Vandenberg et al., 2012; vom Saal, 2016).

Life-History is Impacted by the Intrauterine Position (IUP) Phenomenon

There are a large number of studies showing that naturally occurring variation in the blood levels of testosterone and estradiol in mouse, rat and gerbil fetuses, due to being positioned in utero between male fetuses (2M fetuses) or between female fetuses (2F

fetuses), leads to phenotypic differences that impact life history (vom Saal, 1989, 2016; Ryan and Vandenberg, 2002). Numerous studies have identified neuro-behavioral, reproductive and metabolic traits that are related to proximity to another fetus of the same or opposite sex, including in human twins (vom Saal, 2016).

During the fetal period of sexual differentiation, male fetuses have higher serum concentrations of testosterone than females, while in some species, such as house mice (*Mus musculus domesticus*), female fetuses have higher serum concentrations of estradiol than males (Fig. 1); there is also similar evidence in for a sex difference in serum estradiol in human fetuses during the second trimester when sexual differentiation is occurring (Reyes et al., 1974). Near the end of gestation in rhesus monkeys, female fetuses have almost twofold higher concentrations of estradiol than male fetuses (reviewed in vom Saal, 1989). Whereas 2M mouse fetuses (male or female) have significantly greater plasma concentrations of testosterone, 2F fetuses have significantly higher serum concentrations of estradiol relative to other fetuses of the same sex; animals next to a single male or female fetus have intermediate serum levels of testosterone and estradiol (Fig. 1); this is also the case for rats (Timms et al., 2002) and Mongolian gerbils (Clark et al., 1991). We showed that the intrauterine position phenomenon is due to transport of steroids via diffusion through the amniotic fluid and then across the chorionic and amniotic membranes separating adjacent fetuses (Even et al., 1992). A critical aspect of the intrauterine position phenomenon is that the positioning of fetuses in the uterus has been shown to be a random event (vom Saal, 1981), thus precluding the possibility that there are systematic genetic differences between fetuses that develop between males versus those that develop between females. However, genotype significantly impacts the functioning of the endocrine system during sexual differentiation, and phenotypic differences due to IUP are not found in inbred mouse strains, but have been reported in a number of outbred stocks (Svare et al., 1984; Ryan and Vandenberg, 2002). The molecular basis for the loss of IUP effects due to inbreeding have not been determined.

Another interesting phenomenon in rats and mice is that blood flow in the uterine artery and vein is bi-directional (Fig. 1), due to the fact that blood enters the uterine loop artery at both the cranial end from the descending aorta and the caudal end from the internal iliac artery; the uterine vein transports blood bi-directionally as well (vom Saal and Dhar, 1992; Even et al., 1994; Coe et al., 2008). The bi-directional blood flow in the rodent uterus leads to fetuses in the middle of a uterine horn being smaller than fetuses at either end due to reduced blood flow at the center of the uterine artery. While uterine blood flow impacts fetal growth, the transport of sex hormones between adjacent fetuses in rodents is unrelated to the direction of blood flow in the uterine artery and vein (Even et al., 1992).

Effects of IUP in Females

Experimental Animal Studies

Table 1 lists the numerous effects of developing between male or female fetuses that have been documented in female mice; many of these effects have also been found in gerbils, as well as in some studies with rats and rabbits. Effects due to IUP include genital morphology, timing of puberty, length of estrous cycles, age at cessation of fertility, sex ratio of litters, production of and response to pheromonal cues, sexual attractiveness to males, sexual receptivity when mounted, maternal behavior, postpartum aggression (defense of pups), interfemale aggression, size of home range, daily activity level, and body weight; most of these effects have previously been reviewed (vom Saal, 1981, 1989, 2016; vom Saal et al., 1999; Ryan and Vandenberg, 2002).

Differences between 2F and 2M female mice are what would be predicted. The effects of elevated testosterone during sexual differentiation on 2M females is consistent with a shorter period of fertility and longer estrous cycles in female rats and mice administered testosterone during early postnatal sexual differentiation, which is referred to as the delayed anovulatory syndrome (Mobbs et al., 1985). Androgenized 2M female mice, gerbils and rats show enlarged ano-genital distance (AGD), which is a well-known bioassay for fetal testosterone levels in males as well as females in rodents (Clemens et al., 1978; vom Saal and Bronson, 1978; Ryan and Vandenberg, 2002), rabbits (Banszegi et al., 2009), as well as in humans (Barrett et al., 2013). Reduced androgen exposure in male fetuses and shorter ano-genital distance predicts reduced adult semen quality in men (Mendiola et al., 2011). The difference in AGD observed at birth due to IUP persists into adulthood in mice (vom Saal and Bronson, 1978; Ryan and Vandenberg, 2002), and is eliminated in rats by maternal treatment with the antiandrogen Flutamide during pregnancy (Clemens et al., 1978). In swine, females born in litters with a high proportion of males had a longer AGD relative to females in litters with a low proportion of males (Drickamer et al., 1997).

An interesting aspect of IUP findings is that models predict that IUP in females may provide a basis for population cycles (irruptions and crashes) in small mammals, whereas most prior research had focused (unsuccessfully) on rapid changes in gene frequency as the mediator of irruptions and crashes in small mammal populations (vom Saal, 1984; Cowell et al., 1998).

Fetal differentiation of the mammary gland in mice is influenced by intrauterine position, with 2M females showing an increase in mammary gland duct development relative to 2F females on gestation day 18. An increase in mammary gland density is associated with mammary gland cancer later in life (Vandenberg et al., 2007).

Sex ratio of litters in Mongolian gerbils and mice varies as a function of prior intrauterine position of a female. 2M females produce male-biased litters and 2F females produce female-biased litters, although 2M and 2F females (mice and gerbils) have the same number of pups, so this phenomenon is not due to differential mortality of males and females in utero (Vandenberg and Huggett, 1994; Clark and Galef, 1995). Thus, 2M females produce more offspring that develop next to male fetuses relative to 2F females, which are more likely to produce offspring that develop next to female fetuses. This is an example of multigenerational transmission of phenotype through a novel, but still undetermined, mechanism.

Table 1 Effects on female mice (and in most cases also gerbils, rats, and rabbits) of developing in utero between female fetuses (2F) and male fetuses (2M)

<i>Effect of IUP</i>	<i>2F Females</i>	<i>2M Females</i>
Serum steroid concentrations during fetal life		
Testosterone		↑
Estradiol	↑	
Adult serum progesterone concentrations		↑
Postnatal morphology		
Perineum: ano-genital distance		↑
Body weight		↑
Mammary gland ducts		↑
Adult reproductive performance		
Earlier puberty	↑	
Shortest most regular estrous cycles	↑	
Longest most irregular estrous cycles		↑
Reproductive aging: longer period of fertility	↑	
Sexual attractiveness to males	↑	
Increased sexual activity (receptivity)	↑	
Female-biased sex ratio of litters	↑	
Male-biased sex ratio of litters		↑
Adult behavior		
Aggression		
Postpartum defense of pups		↑
Aggression toward other females		↑
Territorial/scent marking		↑
Size of home range		↑
Maternal behaviors	↑	
Daily activity	↑	
Enzyme and gene activity		
Preputial gland β glucuronidase activity		↑
Hepatic 7 α -hydroxylase and 5 α -reductase activity	↑	
ER α mRNA in hypothalamic ventromedial nucleus		↑

↑ indicates an increase associated with fetal intrauterine position. Not all effects were seen in all species. In general, 2M females show a phenotype more similar to males for traits that are sexually dimorphic.

Epidemiological Studies of IUP Effects in Human Females

The first evidence for an effect on women of developing with an opposite-sex versus same-sex twin was that developing with an opposite-sex twin significantly masculinized otoacoustic emissions, which are sounds produced by the motion of the cochlea's sensory hair cells (McFadden, 1993). This finding is particularly interesting because otoacoustic emissions represent a sexually dimorphic trait established during fetal life that does not change as a function of postnatal experience. McFadden reported that overall, males show fewer emissions than females, and females with an opposite-sex twin showed fewer emissions than same-sex twin females. Another interesting morphological trait that is significantly masculinized in females that develop with an opposite-sex twin is the eruption patterns of the incisors, upper first molars, and lower canines. These eruption patterns were found to be significantly delayed (masculinized) in opposite-sex twin girls relative to same-sex twin girls (Heikkinen et al., 2013).

A novel study described effects on human females of developing in utero with a male versus a female co-twin by examining historical data from Finland concerning age at marriage and lifetime production of offspring in women who lived during the 18th and 19th centuries (Lummaa et al., 2007). Women born with an opposite-sex twin (whether or not the male died at birth) married later and produced fewer offspring relative to females born with a same-sex twin. The consequence for women born with in utero proximity to a male or female twin was remarkably similar to effects of intrauterine position in mice on lifetime fecundity (Table 1): 2M female mice show later onset of puberty, earlier onset of the cessation of producing live pups, longer, and more irregular estrous cycles, are less sexually attractive and less receptive to males relative to 2F females (vom Saal, 1989). Mertice Clark and colleagues have reported similar findings for Mongolian gerbils in a large number of studies, many reviewed in (Ryan and Vandenberg, 2002). In swine, females born in litters in the highest tertile for proportion of males in the litter also had reduced fecundity relative to females in the lowest tertile for proportion of males (Drickamer et al., 1997).

In contrast to the findings by Lummaa, a study of contemporary young Finnish women did not find significant effects of developing with an opposite-sex twin on the timing of puberty or fertility between age 15 and 28 (Rose et al., 2002). These findings are consistent with another report of no effect on female fertility of developing in utero with an opposite-sex twin in contemporary populations in Australia, the Netherlands, and the United States (Medland et al., 2008). My hypothesis (vom Saal, 2016) is that the absence of significant findings in current studies of IUP effects in humans could be due to world-wide exposure during

development to environmental pollutants referred to as endocrine disrupting chemicals (EDCs). Differential exposure to EDCs today versus prior to the chemical revolution in the mid-20th century, might interfere with the differences in fertility identified by Lummaa. EDCs have been proposed by the Endocrine Society to be a factor in changes in fetal development, fertility, as well as the incidence of many diseases that have markedly increased since the mid-20th century (Gore et al., 2015).

Neuro-behavioral effects of IUP in women

Sexually dimorphic behaviors have been studied in men and women in relation to whether they had a same-sex or opposite-sex twin. Sensation seeking is a sexually dimorphic personality trait involving varied, novel and intense sensations, with males scoring higher on this trait than females. People who are sensation or thrill seekers tend to engage in risk-taking behaviors such as gambling, drinking, smoking, and illicit drug use. The impact on women of developing in utero with an opposite-sex twin on sensation seeking behavior has been examined in studies with similar results (Resnick et al., 1993; Slutske et al., 2011). Women who developed in utero with an opposite-sex twin had significantly higher sensation seeking scores than females from same-sex twin pairs, suggesting masculinization of this trait due to exposure to elevated testosterone from the male co-twin. Importantly, the psychosocial hypothesis that this could be related to having a near-in-age brother was ruled out as a factor in this finding, similar to the findings by Lummaa (Slutske et al., 2011).

In another study, a sex difference in aggression proneness was observed, and girls with an opposite-sex twin showed a more masculine pattern of aggression proneness than girls with a same-sex twin (Cohen-Bendahan et al., 2005). It is well documented that across many types of mammals studied (rodents, monkeys, humans), play behavior is influenced by fetal testosterone exposure. This led to a study comparing play behavior in same-sex and opposite-sex twin 3–8-year-old girls, but no significant differences were observed (Henderson and Berenbaum, 1997).

Effects of Intrauterine Position in Males

Experimental Animal Studies

Table 2 lists the numerous effects of IUP on morphology, physiology, and behavior in male mice and gerbils (intermale aggression, scent/urine marking, sexual behavior, attractiveness to females, parental behavior/infanticide, size and functioning of reproductive organs, size of home range, and daily activity level) that have previously been reviewed (Ryan and Vandenberg, 2002). These

Table 2 Effects on male mice (and in most cases also gerbils, rats, and rabbits) of developing in utero between female fetuses (2F) and male fetuses (2M)

Effect of IUP	2F Males	2M Males
Serum steroid concentrations during fetal life		
Testosterone		↑
Estradiol	↑	
Serum steroid concentrations in adulthood		
Testosterone		↑
Estradiol	↑	
Postnatal morphology		
Perineum: ano-genital distance		↑
Body weight		↑
Size of seminal vesicles		↑
Size of the prostate	↑	
Adult behavior		
Size of home range		↑
Aggression		
Aggression toward other males		↑
Aggression toward pups (infanticide)	↑	
Parental behavior toward pups		↑
Sexual activity	↑	
Daily activity	↑	
Enzyme activity		
Preputial gland β glucuronidase activity		↑
Seminal vesicle and prostate 5 α -reductase		↑
Hepatic NADPH cytochrome <i>c</i> reductase activity		↑
Prostate androgen receptors	↑	

↑ indicates an increase associated with fetal intrauterine position. Not all effects were seen in all species. An increase in 2F males compared to 2M males suggests developmental effects on some outcomes of elevated fetal serum estradiol, which has been experimentally demonstrated for the brain/behavior, and prostate.

findings demonstrate that in male as well as female rodents, small changes in serum levels of steroids can alter neuro-behavioral and reproductive system development. In swine, there is evidence for an increase in aggression and dominance status in 2M males relative to 2F males when competing for food, which led to increased weight gain in 2M relative to 2F adult boars; however, when fed individually, there was no difference in body weight due to prior IUP (Rohde Parfet et al., 1990). The few studies involving human twins that have sought to determine effects on males born with an opposite-sex twin have not reported any significant findings.

An important issue is that 2M and 2F male mice differ in their serum estradiol as well as testosterone concentrations, and some effects of IUP have been shown to be due to differences during fetal life in serum estradiol, while other effects appear to be related to fetal serum levels of testosterone (Fig. 1).

Association of IUP with altered serum testosterone in adulthood in male Mongolian gerbils

The random pulsatile nature of testosterone secretion in adult male mice renders the measurement of testosterone in a single blood sample essentially meaningless. However, we did measure serum testosterone in 2M and 2F male Mongolian gerbils, since they do not show evidence of the release of testosterone in large episodic pulses. Gonadally intact 2M male gerbils had elevated serum testosterone relative to the 2F male siblings (Clark et al., 1992). In gerbils, treatment via a subcutaneous Silastic capsule with the same dose of testosterone in castrated 2M and 2F males eliminated the difference in serum testosterone between intact 2M and 2F males, but there were still differences in scent marking (2M > 2F) due to IUP (Clark et al., 1993). These findings show that the secretion of testosterone in adult males can be impacted by the hormonal environment during fetal life, and there is a large literature that estrogenic and antiandrogenic environmental endocrine disrupting chemicals can lead to altered testosterone secretion and spermatogenesis in males (vom Saal, 2016).

Association of IUP with altered 5 α -reductase activity in seminal vesicles of male mice

The finding that a 2F male mouse fetus reliably has the greatest serum concentrations of estradiol and the lowest serum concentrations of testosterone relative to other male fetuses initially led to the prediction that 2F males would show a postnatal phenotype typical of fetal androgen deficiency. Analysis of the adult seminal vesicles, that differentiate from the distal portion of the embryonic Wolffian ducts, confirmed this prediction. We weighed the blotted seminal vesicles from gonadally intact 2M and 2F adult mice and found that the seminal vesicles from 2M males were significantly larger (Nonneman et al., 1992). We then measured seminal vesicle 5 α -reductase activity in intact and castrated + testosterone-treated 2M and 2F males and found that 2F males had significantly lower 5 α -reductase activity and smaller seminal vesicles relative to 2M males, even when castrated and implanted with a capsule containing testosterone (vom Saal, 2016). The effect of IUP on seminal vesicles was thus not mediated by possible differences due to IUP in serum testosterone in adulthood. In adult mice seminal vesicle fluid influences sperm motility, and removal of the seminal vesicles decreases fertility (Peitz, 1988); seminal vesicle fluid plays a role in semen coagulation, sperm motility, stability of sperm chromatin and suppression of the immune activity in the female reproductive tract (Gonzales, 2001).

Association of IUP with altered fetal prostate gland genesis and prostatic androgen receptors in adulthood in male mice

In contrast to the finding that 2F males had smaller seminal vesicles relative to 2M males, the finding that 2F male mice (Nonneman et al., 1992) and rats (Timms et al., 1999) had larger prostates than 2M males was initially considered implausible. One reason for this was that male rodents treated with high, supra-physiological doses of estrogen during fetal/neonatal life are markedly demasculinized, including having a small prostate (vom Saal et al., 1997). However, these findings emphasize the importance of hormone dose and led to what is now known in toxicology as the “low dose hypothesis.” The key issue is that endogenous estradiol and chemicals that can mimic or interfere with endogenous estradiol or testosterone can have effects at extremely low dose that are opposite to effects observed at high, supra-physiological toxic doses, resulting in inverted U dose-response relationships (Vandenberg et al., 2012).

An interesting finding was that adult 2F male mice that had enlarged prostates also had elevated prostate androgen receptors (about a three- to fourfold difference) but reduced 5 α -reductase activity (by about one-third) relative to 2M males (Nonneman et al., 1992). It thus appears that the increase in androgen receptors is the dominant factor that impacted prostate gland genesis and adult prostate size. In the seminal vesicles, 5 α -reductase was reduced in 2F males but there was no difference between 2M and 2F males in seminal vesicle androgen receptor number (Nonneman et al., 1992). Taken together, these data confirm numerous other findings that during fetal life, gonadal steroids “program” the activity of steroid metabolizing enzymes and steroid receptors in target tissues, with life-time consequences.

Summary

The effects of IUP in litter-bearing animals have predicted significant effects in women born with an opposite-sex twin in comparison to women born with a same-sex twin, while effects on the male siblings in these twin studies have not been found in the very few studies that have included examination of males. Importantly, there is consistency of findings regarding the effects of IUP on a wide variety of traits in both males and females in litter-bearing mammals (mice, gerbils, rats, rabbits, and swine). The IUP phenomenon has significantly impacted our understanding of the exquisite sensitivity of fetuses to extremely small changes in gonadal steroids during the critical period of sexual differentiation, and that the very small differences in testosterone and estradiol can alter the life history of both males and females.

COMPARATIVE MAMMALIAN FEMALE REPRODUCTION

Metatheria: Marsupials

Marilyn B Renfree and Geoffrey Shaw, The University of Melbourne School of BioSciences, Victoria, Australia

© 2018 Elsevier Inc. All rights reserved.

Glossary

Altricial young A new born young that is relatively undeveloped at birth, although particular features may be more advanced.

Embryonic diapause A regulated, reversible slowing or halt in embryonic development at the blastocyst stage.

Macropodid A member of the kangaroo and wallaby family of marsupials.

Pouch An abdominal fold of skin around the mammary areas on a marsupial.

Semelparity Having a single breeding cycle in a lifetime.

Introduction

Therian mammals (**Fig. 1**) consist of the marsupials and eutherian mammals that diverged from each other about 160 million years ago. There are about 340 living species (**Table 1**), representing about 6% of the world's mammalian fauna. Extant marsupials are found in Australasia and South America, with only one species, the opossum, extending into North America. They are a diverse group occupying almost every ecological niche from the tropical rainforest to alpine to desert, with aquatic, arboreal including gliders, and terrestrial herbivores, omnivores and carnivores (**Tyndale-Biscoe and Renfree, 1987**).

Fig. 1 Tammar wallaby (*Macropus eugenii*) female with a large, nearly weaned pouch young.

Table 1 Marsupial orders

<i>Marsupial Families</i>	<i>No. of species</i>
Didelphidae: American opossums	103 species
Caenolestidae: Shrew opossums	7 species
Microbiotheridae: Monito del Monte	1 species
Dasyuridae: Native cats, marsupial mice	75 species
Peramelidae: Bandicoots	19 species
Burramyidae: Pygmy possums	5 species
Acrobatidae:	2 species
Tarsipedidae: Honey possum	1 species
Petauridae: Gliding possums	11 species
Pseudocheiridae: Ringtail possums	17 species
Phalangeridae: Possums	28 species
Phascolarctidae: Koala	1 species
Vombatidae: wombats	3 species
Macropodidae: kangaroos, wallabies and rat kangaroos	65 species

**Fig. 2** Neonatal tammar wallaby attached to a teat in the pouch.

Marsupials are most clearly distinguished from the eutherian mammals by their mode of reproduction (Renfree, 2006). The new-born young are altricial, relatively under-developed, born at a stage when most eutherians are still fetuses in the uterus. Those features essential for post-natal survival, such as a digestive tract, respiratory system, and functional forelimbs needed to climb to the pouch, are disproportionately well developed at birth (Fig. 2). However, by the end of the long lactation, marsupial young are as well developed as equivalent eutherian mammals at weaning. Their reproduction has many remarkable features (Box 1).

Reproductive Anatomy

A difference between eutherian mammals and marsupials in the early development of the urogenital ducts in the embryo has had profound effects on the anatomy of the adult male and female reproductive tracts. In marsupials, the ureters enter the bladder medially. In females, this keeps the paired female genital ducts apart, while in eutherians they enter laterally so that the paired genital ducts can fuse to form a single vagina (Fig. 3). As a result, female marsupials have a complex vaginal structure with paired lateral vaginae and a new connective tissue strand medially which forms the birth canal or median vagina (Figs. 3 and 4(a)).

Box 1 Marsupial record holders

In the mammalian reproductive Olympiads marsupials hold many records. The diminutive (8–10 g) honey possum, *Tarsipes rostratus* (left), has the most gold medals. Almost five percent of their body is testes (the human equivalent is a man with two footballs in his scrotum!). Perhaps they need this size to accommodate the largest of mammalian sperm –360 μm long (right). Despite these 2 records, females are socially dominant, yet they give birth to the smallest mammalian baby, weighing in at less than 5 mg. They may have the shortest period of organogenesis (conclusive data is not available), but the shortest established period of organogenesis in any mammal is 64 h in another marsupial species, the Tasmanian devil, *Sarcophilus harrisii*, at 64h (Fig.10). Another marsupial the bandicoot, may have the shortest recorded gestation length –12.5 days (Fig.10). As more is discovered about these remarkable mammals there are bound to be more records broken.

Fig. 3 Comparison of the urogenital tracts of marsupials, monotremes and eutherians. Note the relative location of the ureters, which prevents the fusion of the embryonic paired reproductive ducts to form a single vagina as in eutherians. The vaginae fuse cranially to form the anterior vaginal expansion, and a connective tissue strand between this and the urogenital sinus opens to form the median vagina, or birth canal, at first birth. Redrawn from Renfree, M.B., 1993. Ontogeny, genetic control and phylogeny of female reproduction in monotreme and therian mammals. In: Szalay, F.S., Novacek, J.J., McKenna, M.C. (Eds.), *Mammal Phylogeny*. Springer-Verlag, New York. pp. 4–20.

Fig. 4 Urogenital tracts of typical male and female marsupials. In females (a) the two uteri are completely separate, and have separate cervixes opening into the anterior vaginal expansion. Male (b) lacks seminal vesicles and coagulating glands, but has a large prostate and Cowper's glands. In most species the adult testes lie in a pendulous scrotum on the abdomen cranial to the penis, which when erect extends from the common urogenital opening. Redrawn from Renfree, M.B., 1994. Endocrinology of pregnancy, parturition and Lactation of marsupials. In: G.E. Lamming (Ed.), *Marshall's Physiology of Reproduction*, fourth ed. vol. 3: Pregnancy and lactation. Churchill Livingstone Edinburgh, London. pp. 677–766.

The characteristic that gives marsupials their name, the pouch, is not found in all marsupials. In no species does the male have a pouch, and pouches are also absent in females of some didelphids, caenolestids (South American) and dasyurids (Australian).

Male reproductive anatomy is similar to that of eutherians and the testis descends to the scrotum in most species, but the scrotum is always cranial to the penis (Fig. 4(b)). There are no seminal vesicles, ampullae or coagulating glands, but the vasa

deferentia enter into the anterior end of a large carrot-shaped prostate. The sperm undergo maturation in the epididymis. In the American marsupials, with the exception of one species, *Dromiciops*, the spermatozoa form into pairs in the epididymis by intimate association of the acrosomes. Sperm pairs separate in the oviduct and fertilisation is achieved by a single sperm. All Australian species have single sperm.

In marsupials there is a single external urogenital opening which is similar in appearance in both males and females. However, the female opening is not a cloaca, and there are two sphincters, one for the urogenital opening and the other for the rectum. Unlike in eutherians, in which the scrotum differentiates through fusion of the labio-scrotal folds behind the phallus, the marsupial scrotum forms on the abdomen anterior to the phallus. The pouch and scrotum are probably not homologous but arise from adjacent morphogenetic fields on the abdomen. Some marsupials such as the marsupial mole have inguinal testes, but none are testicond.

Patterns of Reproduction

Most marsupials are seasonal breeders, with reproduction timed so that the emergence of the young from the pouch coincides with the most favourable time of year. Photoperiod, nutrition, temperature and other factors may play a role. Some small dasyurid species are semelparous and the males die off after the breeding season (Fig. 5).

Marsupial reproductive patterns fall into 4 major groups.

- Group 1: Polyovular, polyoestrous species in which gestation occupying less than 60% of the oestrous cycle coinciding with the luteal phase. Oestrus and ovulation are suppressed during lactation (e.g., possums).
- Group 2: Polyovular, polyoestrous, with ultra-short gestation occupying less than the luteal phase which is prolonged into lactation (e.g., bandicoots, opossums).
- Group 3: Monoovular, polyoestrous species with gestation extending into the follicular phase, and gestation occupying 94%–109% of the oestrous cycle length. Postpartum oestrous occurs with lactation controlled diapause in most species (kangaroos, wallabies and rat-kangaroos).
- Group 4: Polyovular, polyoestrous with a very prolonged pre-luteal phase and gestation which includes a long period of embryonic diapause after *post partum* oestrus (e.g., honey possum, some small possums).

In all species, pregnancy is short relative to the length of lactation. The marsupial oestrous cycle varies from 22–42 days (mean across known species 28 days) (Fig. 6). The life of the corpus luteum is not prolonged by the presence of the conceptus, and because the length of gestation is shorter than the oestrous cycle in all but one species (the swamp wallaby, *Wallabia bicolor*), anatomical and endocrinological changes of pregnancy and the oestrous cycle are similar. This situation in marsupials gave rise to the term “pseudopregnancy”. This term was subsequently adopted by reproductive biologists in the 1920s to refer to the condition that follows sterile mating in the rabbit and rat. In most species, the young are born towards the end of the luteal phase so that the mothers return to oestrus is suppressed by the sucking of the neonate. By contrast, in the macropodids (kangaroos and wallabies) the single young is born at the end of the pro-oestrous phase and ovulation and fertilisation occur *post partum*. The resulting conceptus

Fig. 5 Semelparity is a unique marsupial life-history strategy seen in some dasyurid species. The best known example is *Antechinus stuartii*. The young are weaned in summer (the timing varies in different locations in Australia), becoming sexually mature in late autumn. Over the next 3 months the males become increasingly territorial, and much fighting and agonistic behaviour occurs as females enter their breeding season. By the end of the breeding season, the males almost all die of stress related diseases. So that no males are alive by the time the females are having their litters. For about 2 months the young are permanently attached to the teats, and then for a further 2 months are left in a nest whilst their mother forages. The young are then weaned, and they disperse, becoming sexually mature before the next annual breeding cycle. Few females survive to breed for more than 2 years.

Fig. 6 Summary of the patterns of oestrous cycle and gestation in marsupials. In most species gestation is much shorter than the oestrous cycle, and the sucking stimulus from the newborn young in the pouch inhibits ovulation until after weaning. In most macropodids pregnancy is almost as long as the oestrous cycle, and the sucking stimulus does not suppress oestrus which can occur a few hours after birth. The resulting conceptus enters diapause, preventing problems of pouch occupancy by 2 young of different ages.

Fig. 7 Embryonic diapause in the tammar wallaby. In the breeding season – between the summer solstice and winter solstice – a sucking stimulus acts via a neural pathway to increase prolactin secretion. In the non-breeding season photoperiodic signals acting via melatonin produced in the pineal regulate prolactin. High prolactin levels prevent the CL from secreting progesterone. Removal of the sucking or seasonal inhibition, or treatment with prolactin inhibiting drugs allows progesterone to rise, stimulating the uterine secretions which allow the embryo to reactivate.

develops to an 80–100 cell blastocyst and then enters a dormant state known as embryonic diapause (Fig. 7). Embryonic diapause also occurs in some small possums.

Diapause is maintained by lactation, which stimulates prolactin release from the pituitary, which in turn inhibits the development of the corpus luteum. When the young weans, or if the young is prematurely lost, prolactin falls allowing the CL to reactivate. Luteal progesterone then stimulates the uterus to reactivate the embryo (see Fig. 7). The corpus luteum, although held in quiescence by prolactin itself, prevents a new ovulation in the opposite ovary.

Pregnancy

The endocrinology of reproduction in marsupials is broadly similar to that of eutherian mammals, but with some notable differences. The CL functions autonomously, and does not require pituitary support through pregnancy, although the pituitary is needed to supply gonadotrophins for follicular development. The corpus luteum secretes progesterone throughout the gestation period, but in the 3 species in which it has been investigated, progesterone is not needed for the maintenance of pregnancy after blastocyst expansion has been initiated, even though there little or no placental progesterone secretion. However it is needed for birth (see section **Parturition**) (Renfree and Shaw, 1996). In the macropodids, reactivation from diapause is associated with a rise in plasma progesterone concentrations with a peak about day 5 (depending on species) after removal of the pouch young (Renfree and Shaw, 2000, 2014; Renfree and Fenelon, 2017). Progesterone levels then drop, rising again to a plateau between about day 10 and 26, with a precipitous fall at birth.

Embryology

Marsupial oocytes are relatively large compared to those of eutherian ranging from about 150 to 250 μm diameter. As well as the primary plasma membrane the egg has a zona pellucida secreted in the developing follicle, and by tertiary membranes – the mucoid coat and a keratinous shell membrane secreted by the oviduct and uterus (Fig. 8). Sperm are rapidly transported up the lateral vaginae, not the median vagina, and reach the ampulla within 2–5 h. Fertilisation occurs in the oviduct, and passage to the uterus is rapid (less than 48 h).

Cleavage proceeds, without a morula stage, to the formation of a unilaminar blastocyst without an inner cell mass (Frankenberg *et al.*, 2013, 2016). Formation of the primitive streak occurs on the surface of the embryonic vesicle in a manner akin to the avian embryo. Duration of organogenesis is short and relatively constant (Figs. 9 and 10), even in species of widely differing body masses, ranging from 4 days in the dasyurid *Antechinus* to about 10 days in macropodids.

Molecular studies of early development in marsupials provide an interesting contrast to eutherian mammals. Whilst the blastocyst lacks an inner cell mass, distinct subpopulations of cells become distinguished by upregulation of lineage specific transcription factors such as POU2 and POU5F1 to form a cell population with similar developmental fate to the inner cell mass of eutherians. Patterns of expression and localisation of CDX2, YAP and WWTR1 differed significantly from the mouse but had similarities with humans and cattle (Frankenberg *et al.*, 2013, 2016). These studies are revealing considerable plasticity in the mechanisms underlying early lineage specification in mammals.

Marsupials are placental mammals with well-developed placental exchange mechanisms, although these are only established in about the last third of gestation (Renfree, 2010; Guernsey *et al.*, 2017). Most marsupials have a choriovitelline (yolk sac) placenta but some have an invasive chorioallantoic placenta as well. Four major placental types have been recognised ranging from those in which the allantois remains closed in the folds of the yolk sac (kangaroos, wallabies, possums and opossums), to those in which the

Fig. 8 Marsupial egg coats. The zona pellucida forms in the follicle. The mucoid coat and shell are laid down in the oviduct and the uterus. Sperm are visible embedded in the mucoid coat.

Fig. 9 Representative stages in the embryology of the opossum. Note the lack of an inner cell mass, superficial development, and the relative development of the forelimbs of the term fetus (stage 35). (Reproduced from Renfree, M.B., 1994. Endocrinology of pregnancy, parturition and Lactation of marsupials. In: G.E. Lamming (Ed.), Marshall's Physiology of Reproduction, fourth ed. vol. 3: Pregnancy and lactation. Churchill Livingstone Edinburgh, London. pp. 677–766).

Fig. 10 Timing of embryogenesis and organogenesis in some marsupials. The species represented are (top to bottom) Tasmanian devil, Antechinus, bandicoot, American opossum, brush tail possum, tammar wallaby, potoroo.

allantois forms a discoid with a long umbilical cord in addition to the choriovitelline placenta. All bandicoots have this invasive placentation in which maternal and fetal cells fuse to form a syncytium. The placenta maintains a nutritive, excretory and metabolic function during gestation. As in eutherian mammals, genomic imprinting of several critical growth factor genes is essential for proper placental function and embryonic development. While the placenta of the tammar wallaby has minimal steroid synthetic activity, it does have considerable capacity for prostaglandin synthesis and also expresses other hormones including prolactin, relaxin, LH β , GH, GH-R and IGF2. The compositions of the yolk sac, amniotic and allantoic fluids are unique to each compartment, and the yolk sac contains high concentrations of cortisol at term.

Parturition

Despite the small size, a fetal signal is necessary to trigger birth as in many eutherians. The mechanisms involved have been investigated in very few species, but the best known is the tammar wallaby (Fig. 11; Renfree, 1994; Shaw and Renfree, 2006).

Labour is brief, and coincides with the onset of a characteristic parturient behaviour which is controlled by prostaglandins (Fig. 12). After the fetuses are expelled from the urogenital sinus they climb rapidly up to the pouch (or abdomen in pouchless forms), where they attach to a teat.

The neonate is altricial. Many organs are poorly developed, but the forelimbs, mouth, digestive tract and lungs are comparatively well developed and functional to permit the neonate to climb to the teat, attach, and digest milk (Fig. 2).

Lactation

Lactation is relatively prolonged due to the immaturity of the neonate. Three phases of lactation are recognised, Stages I and II being the equivalent of lactogenesis stage I of Eutheria. There are dynamic changes in milk composition throughout the whole of lactation that correlate with changes in needs of the young and ultimately control its growth and development.

Fig. 11 Hypothetical model for the endocrine control of parturition in the tammar. Near term prostaglandin production in the endometrium and placenta increases. There is also a sharp rise in myometrial receptors for oxytocin. Relaxin, together with progesterone and possibly prostaglandins cause cervical softening and preparation of the birth canal. An increase in cortisol production by the fetal adrenal may stimulate placental or uterine PG production may initiate contractions. PG also acts centrally to initiate parturient behaviour, and induce release of oxytocin (or mesotocin) which further stimulates uterine contractions. The interactions between these hormones sets up a positive feedback cycle that ensures rapid evacuation of the uterus and delivery of the fetus. (Reproduced from Renfree, M.B., 1994. Endocrinology of pregnancy, parturition and Lactation of marsupials. In: G.E. Lamming (Ed.), *Marshall's Physiology of Reproduction*, fourth ed. vol. 3: Pregnancy and lactation. Churchill Livingstone Edinburgh, London. pp. 677–766).

Fig. 12 Tammar wallaby in the characteristic birth posture which is adopted minutes before delivery. The young must climb from the urogenital opening to the pouch in order to survive (photo by G. Shaw).

Fig. 13 Changes in milk composition through lactation in a marsupial. In many species of macropodid the decrease in sucking in late lactation terminates diapause, so a new young may be born and receive milk rich in carbohydrate from one gland, whilst the young at foot is getting milk rich in lipid and low in carbohydrate from an adjacent gland. This is known as concurrent asynchronous lactation. Redrawn from Green & Merchant, in Tyndale-Biscoe, C.H., Janssens, P.A. (Eds.), 1988. *The Developing Marsupial: Models for Biomedical Research*. Springer Verlag, Berlin.

In early lactation the milk has a high protein, low fat composition, while later in lactation there is a high fat, low protein milk (Fig. 13). The particular proteins, amino acids, fats and carbohydrates are all precisely regulated, and in some of the continuously breeding kangaroos, adjacent mammary glands supporting a small new young and a large young at foot produce milk of different compositions, a phenomenon known as concurrent asynchronous lactation.

Studies in which young of various ages were cross-fostered to mothers at different stages of lactation have shown the critical importance of synchrony between developmental stage of the young and the milk composition it receives. Transferring a young to a mother at a later stage of lactation can accelerate both growth and development (Menzies *et al.*, 2012; Hetz *et al.*, 2015). Transfer to an earlier stage of lactation retards growth.

Milk contains many bioactive components including PDGF, IGFBP5, IGFBP1 and EGFL6. Cross fostering studies have highlighted the importance of milk bioactives in development of organs including lungs and stomach.

Development

The immaturity of the new-born marsupial makes it an excellent model for some developmental studies (Pask and Renfree, 2010; Graves and Renfree, 2013; Grant *et al.*, 2012; Renfree *et al.*, 2011). One that has received substantial attention is sexual differentiation, which occurs mostly post-natally. Most aspects are similar to eutherians. They have a homologue of *SRY*, the testis determining gene on the Y chromosome. The differentiating testes secrete AMH and androgens which control virilisation. A notable exception is in the control of the pouch, mammary glands and scrotum (Renfree *et al.*, 2014a). In the tammar wallaby, where most information is available, mammary anlagen develop only in females and scrotal bulges form only in males. These sexually dimorphic structures form at least 4 days before gonadal differentiation, independent of gonadal hormones, as a result of as yet unidentified gene or genes on the X-chromosome. The presence of one X leads to scrotal differentiation, whilst possession of 2 X chromosomes leads to mammary gland (and pouch formation in pouched marsupials) (Figs. 13 and 14). Thus an XO marsupial

Fig. 14 Control of sexual differentiation in marsupials. As in eutherian mammals, the Y-chromosomal gene SRY induces the gonads to form testes and secrete MIS and testosterone, which virilise the internal reproductive tract. In the absence of a Y-chromosome, female gonads form into ovaries, which produce neither testosterone nor MIS, allowing a female internal tract to form. However, the sex-specific differentiation of the mammary anlagen and scrotum is not dependent on SRY nor gonadal hormones. Instead it is regulated by the number of X chromosomes present.

intersex has streak gonads, female internal genitalia, but an empty scrotum rather than a pouch and mammary glands, and an XXY marsupial intersex has a pouch and a penis but no scrotum.

The development of the internal genitalia and phallus is dependent on androgens but the differentiation of gonads, prostate and phallus occurs post-natally and separated in time, making them amenable to experimental manipulation. This allowed endocrine studies that revealed a new synthetic pathway for androgen in tammar wallabies that was subsequently found to be important in sexual development in other mammals including humans and clarifies previously unexplained cases of virilisation in girls with congenital adrenal hypoplasia and 21-hydroxylase deficiency (Wilson *et al.*, 2003).

The postnatal gonadal differentiation has allowed investigation of sex reversal in mammals (Renfree *et al.*, 2014b). In male tammar treated with oestrogen before testicular differentiation starts, both male somatic and germ cells can be sex reversed. Exogenous androgen treatment and castration of developing young at various stages demonstrated that virilisation depends on hormonal imprinting. Androgen action in specific windows of sensitivity preceding the start of morphological differentiation by days or weeks are needed for virilisation of the Wolffian ducts, prostate and especially phallus. Without androgens in these critical windows, for example after castration, virilisation fails leading to poor differentiation and in the case of the phallus, hypospadias. Androgen treatment of females through these windows of sensitivity leads to masculinisation.

X-chromosome inactivation also differs from that in Eutheria, in which X-inactivation is random in the fetus, but the paternal X is inactivated in the trophoblast. In marsupials, the paternal X is inactivated preferentially in both trophoblast and fetus, although the inactivation is tissue specific and leaky. The marsupial X-inactivation gene is a long non-coding RNA analogous to the eutherian *XIST* named *RSX* (RNA-on-the-silent-X). *RSX* is expressed only in females and, like *XIST*, coats the inactive X.

Summary

Marsupials are true mammals that have a distinctive reproductive physiology and developmental pathway. Their reproduction is characterised by short gestation with a fully functional placenta, delivering altricial neonates that depend on a long and sophisticated lactation. Females have a characteristic paired reproductive system and in males the scrotum is cranial not caudal to the penis. In most species of macropodids, and some possums there may be a period of embryonic diapause at the blastocyst stage. Embryonic diapause and early embryogenesis provide fascinating contrasts to eutherians, that are providing new clues to early development. Organogenesis is compressed into the last few days of gestation. The neonate is altricial, and undergoes prolonged development during a complex lactation, in most species held in a pouch. Studies of the control of milk production are leading to new insights into local regulation of mammary physiology, neonatal programming, and obesity. Striking differences in the timing of development have proved especially useful, and led to the demonstration that some aspects of somatic sexual differentiation are independent of gonadal hormones, but rather result from a direct effect of the sex-chromosomal genes. Genetic and genomic studies in marsupials are illuminating the evolution of fundamental processes such as genomic imprinting and X-inactivation that are so essential to mammalian reproduction and development. Because of their unique features, marsupials will continue to make a great contribution to the understanding of reproduction in all mammals.

Glossary

Altrenogest A synthetic progestogen used to synchronize estrus in gilts.

Anestrous sow A sow that fails to come back into estrus after weaning.

Bicornuate uterus Uterus in which there are two long uterine horns (150–200 cm) connected by a common short uterine body (1 cm).

Blastocyst Early stage of embryo development containing an outer trophoblast with inner cell mass and fluid filled center called the blastocoel.

Conceptus Embryo and its extraembryonic placental membranes.

Corpus luteum (CL) Ovarian structure that is formed from the follicle after ovulation that synthesizes and secretes progesterone.

Cystic follicle Large follicle on the ovary that is incapable of ovulation.

Dystocia Difficult birth caused by a large or badly positioned fetus.

Epitheliochorial placentation A noninvasive type of placental attachment in which microvilli of placenta (chorion) and uterine surface epithelium interlock superficially at the maternal-fetal interface in the uterus.

Estrus Period of the estrous cycle when females are sexually active and receptive to mating by the male.

Farrowing rate Percentage of gilts or sows that become pregnant and farrow a litter after insemination.

Follicle Ovarian structure that contains the developing oocyte (egg) and also synthesizes and secretes estradiol to bring the pig into estrus.

Gilt Young female pig.

Luteolysis Functional and structural regression of the corpus luteum causing a decrease in blood progesterone concentrations.

Maternal recognition of pregnancy Period of early pregnancy when a chemical signal(s) produced by the developing conceptus prevents the regression of the corpus luteum to maintain the corpus luteum beyond the normal length of the estrous cycle.

Mesometrial The region of the uterus where the broad ligament containing maternal blood vessels attaches and enters into the uterus.

Morula Early embryo stage of development where multiple blastomeres form a solid ball of cells contained within the zona pellucida.

P.G. 600 A combination of a pregnant mare serum gonadotropin (PMSG) and human chorionic gonadotropin (hCG) that is used to bring prepubertal gilts and postpartum sows into estrus.

Polyestrous Females having multiple estrous cycles throughout the year.

Polytocous Females that give birth to multiple offspring at parturition.

Psuedopregnancy Condition of female where the corpus luteum lifespan is extended beyond the length of the estrous cycle without the presence of a fetus.

Puberty Period of adolescence when a male or female is first able to release gametes.

Sow Adult female pig that has given birth.

Introduction

The domestic pig (*Sus scrofa domesticus*) is a polyestrous, polytocous farm animal species. Modern breeds of domestic pigs typically breed year-round. The European wild boar and feral pigs, however, can display a seasonal (July to September) anestrus related to photoperiod and nutrient availability in their natural (wild) environment. General characteristics of reproduction for the domestic pig are presented in **Table 1**. Gilts (young female pigs before first farrowing) from commercial maternal lines reach puberty at 5–7 months of age and farrow their first litters when they are approximately 1 year old. The length of estrous cycle for gilts and sows (mature females that have given birth) is approximately 21 days (range 18–22 days) with estrus (standing heat) lasting from 24 to 72 h. Ovulation occurs approximately 30–40 h after the initiation of estrus. Gilts and sows are typically inseminated by either hand mating with a boar or by artificial insemination (AI) on the first and second day of estrus.

Gilts and sows ovulate from 20 to 30 ovarian follicles that are 8–10 mm in diameter when mature. Oocytes are released from the ovulatory follicles and transported into the oviduct for fertilization. The cervix of the pig has thick alternating interdigitating pads that lock around the spiral corkscrew shaped glans penis of the boar during mating (**Fig. 1**). Pipettes used for artificial insemination

Table 1 Characteristics of female reproduction in the domestic pig

Age at puberty	5–7 months
Estrous cycle length	18–22 days
Duration of estrus	24–72 h
Time of ovulation	30–40 h after the initiation of estrus; two-thirds to three-quarters of the time through estrus
Number of follicles ovulated	20–30
Gestation length	114–117 days
Age at first farrowing	12 months
Farrowing rate	>85%
Litter size	8–18
Still born rate	<7%
Lactation length	21–24 days
Weaning percentage (weaned/ live born)	>90%
Number of farrowings per sow per year	2.3–2.4
Number of piglets per sow per year	25–30
Number of litters before culling	3–4

(AI) lock into the spiraling cervical rings of the pig to replicate the anatomy of the boar penis. Compared with other farm species, the boar produces an extremely large volume of semen. Semen is diluted and used fresh for AI in pigs. The semen is infused into the cervix or uterus in a relatively large volume over a 5–10 min period.

A high percentage of pigs become pregnant after breeding. The uterus of the pig has a short uterine body (1 cm) with long uterine horns (150–200 cm) that support the extensive placentation of the conceptus (**Fig. 1**). Gestation is approximately 114 to 117 days and litter sizes are typically 8–18 piglets per litter with an average of approximately 12 piglets per litter. Sows are weaned 21–24 days after farrowing. After weaning sows return to estrus within 1 week and they are AI to reestablish pregnancy. The production cycle for

Fig. 1 Picture of pig bicornuate reproductive tract. Drawing by Lydia Michel and Sarah Petty.

a sow, therefore, is approximately 142 days (gestation+lactation+return to estrus). A highly productive sow, therefore, can farrow nearly 2.5 litter per year and produce over 30 piglets per year.

Puberty and the Estrous Cycle

Puberty

Gilts are born with an immature ovary that contains primordial, primary and secondary follicles. Ovarian follicular development depends on gonadotropins (follicle stimulating hormone (FSH) and luteinizing hormone (LH)) that arise from the anterior pituitary under the control of gonadotropin-releasing hormone (GnRH). Circulating concentrations of FSH are elevated until 10 weeks of age and provide an initial stimulus for ovarian follicular development. There is a gradual increase in the number of LH pulses per day with increasing age. The negative feedback effect of estradiol on LH secretion is also reduced over time. The ovary grows and there are successively larger ovarian follicles that secrete greater amounts of estradiol that in turn stimulate growth of the uterus. When ovarian follicles achieve a critical threshold of circulating estradiol then there is an LH surge that triggers first ovulation (puberty) at 5–7 months of age (80–120 kg of body weight). The age at puberty can be influenced by breed, season of the year, nutrition, social environment, and exposure to the boar. A delay in puberty has been observed in the summer months and also when young pigs are confined and crowded in indoor pens. Mixing gilts from different pens or transporting gilts in a truck or trailer can advance the age at puberty if gilts have adequate nutrition. Daily exposure of gilts to boars has a direct effect on advancing puberty in gilts that are between 135 and 160 day of age. Stimulation of puberty by the boar occurs through physical contact, vocalization, and secretion of musk-smelling compounds, 16-androstenes, that give the typical odor of mature boars. Boar odor provides signals to the female for inducing cyclicity and also the strong lordosis response during estrus. The first pubertal estrus in the gilt is generally less fertile with a lesser ovulation rate compared with subsequent estrous cycles. To achieve larger litters, therefore, gilts are typically inseminated at their second or third estrus.

Puberty can be advanced by treating gilts with a combination of pregnant mare serum gonadotropin (PMSG) and human chorionic gonadotropin (hCG) which is marketed under the trade name P.G. 600 (Merck Animal Health; Summit, New Jersey, United States). Prepubertal gilts should be older than 5.5 months of age before treatment. Gilts will show estrus 4–10 days after treatment (average=7 days). Gilts can be inseminated at their first estrus after P.G. 600 or can be inseminated at the next estrus which will increase farrowing rate and litter size.

Estrous Cycle

In domestic farm animals, the estrous cycle is defined as the number of days from initiation of behavior estrus expression to onset of a subsequent estrus. Endocrine changes during the estrous cycle are presented in Fig. 2. There are four stages of the estrous cycle: proestrus, estrus, metestrus, and diestrus. During *proestrus*, circulating concentrations of progesterone decline rapidly. The decrease in progesterone (regression of the corpus luteum) is caused by the episodic release of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) from the uterine endometrium. The regression of the CL and concomitant decline in circulating progesterone is associated with an increase in the frequency of LH pulses that initiates a wave of follicular development. The development of large ovarian follicles increases the circulating concentrations of estradiol and inhibin. The increases in both estradiol and inhibin cause a decrease in circulating FSH

Fig. 2 Diagram of circulating hormone concentrations during the estrous cycle of the pig.

when the pig approaches estrus. High circulating concentrations of estradiol bring pigs into *estrus*; the next phase of the estrous cycle. Pigs display lordosis behavior or “standing heat” when they are in estrus meaning that they will stand still with erect ears when mounted by the boar or following the application of back pressure by a person. Other signs of estrus include swelling and reddening of the vulva, vocalization (estrual grunts), mounting other female pigs and boar-seeking behavior. In response to estradiol, the cervix becomes rigid and the uterine horns are tightly coiled.

The duration of estrus tends to be shorter in gilts (24–48 h) compared with mature sows (24–96 h). Circulating estradiol reaches peak concentrations near the onset of estrus and triggers the LH surge. The LH surge may occur before, during or after the initiation of estrus. High circulating LH concentrations last for about 10 h during the LH surge. Ovulation occurs during a 1–3 h period approximately 30–35 h after the LH surge. In general, ovulation occurs when the estrus period is 70% complete. The fact that the LH surge and ovulation is poorly timed with the onset of estrus makes the timing of AI difficult. Gilts and sows, therefore are typically inseminated two times during estrus and may be inseminated a third time if they are in estrus on day 3. A new animal drug named “OvuGel” (JBSUnited Animal Health; Sheridan, Indiana, United States) was recently introduced. OvuGel is a GnRH agonist that causes an LH surge with ovulation 40–48 h after treatment. OvuGel can be used in a program for single fixed time AI in sows after weaning.

Following ovulation, the granulosa cells and theca cells of the follicle wall become luteinized and form corpora lutea (CL). Initially blood fills the lumen of the ruptured follicle to form the corpus hemorrhagicum (CH) and the CH is eventually replaced by the CL. The *metestrus* phase of the estrous cycle follows as the CL grows, fills the ruptured follicle cavity of the CH, and increases its synthesis of progesterone. The presence of multiple CL (8–11 mm in diameter) on each ovary results in a steady increase in circulating progesterone. *Diestrus*, the period of maximal circulating progesterone follows metestrus and continues for approximately 2 weeks during the estrus cycle. Concentrations of progesterone greater than 30–40 ng/mL are achieved during diestrus. The episodic release of PGF_{2α} from the uterine endometrium and the regression of the CL defines the end of diestrus and beginning of the proestrus phase which leads back to estrus.

Synchronization of Estrus

Reproductive management of farm species typically involves protocols that are used to synchronize estrus in a group of females. Synchronization of estrus is done to reduce the time and labor associated with estrous detection and to facilitate the use of AI. Although exogenous PGF_{2α} is commonly used to regress the CL in cattle, it is not routinely used to synchronize estrus in gilts or sows because the CL does not respond to exogenous PGF_{2α} until after day 12 of the estrous cycle or pregnancy. Estrus in gilts can be synchronized by feeding altrenogest (a progestin) marketed under the trade name Matrix® (Merck Animal Health, Intervet Inc.; Summit, New Jersey, United States) at a dose of 15 mg/day for 14 day. The altrenogest suppresses follicular development so that a synchronous wave of follicular growth occurs in a group of gilts after feeding is stopped. Gilts typically express estrus 4–9 day after the last day of altrenogest feeding.

Breeding

Estrous detection is typically done twice daily using a boar. Gilts or sows that show an interest in the boar and that stand with erect ears when pressure is applied to the back are considered in estrus. Estrus lasts 2–3 days. The reproductive tract of the pig lacks a fornix vagina (blind pocket around the cervical opening) that is present in a number of other farm species (cow, mare and ewe) (Fig. 1). Hand mating of boars to sows or AI of gilts and sows is quite easily accomplished because the fornix vagina is not present. Hand mating or AI is usually done 12–24 h after first detection of estrus and then repeated on the next day. Gilts or sows that are in heat for a third day may be inseminated three times (once for each day in estrus). Artificial insemination is very typically done on swine farms because it conserves semen (allowing one boar to breed many females) and enables producers to purchase semen from superior boars for use on farm. When AI is used, semen is diluted to a volume of 50 mL in extender and a total of 2–3 billion sperm are used for each breeding. A plastic AI pipette attached to a bag of liquid semen is inserted into the vagina and threaded or inserted into the cervical rings. The semen is then slowly infused into the cervix over 5–10 min. Some AI pipettes lock into the cervix and a second catheter is fed through the cervix and into the uterine body for insemination. Intrauterine insemination catheters enable the use of one-half the number of sperm cells per insemination without compromising farrowing rate or litter size. A high percentage of oocytes are fertilized and most gilts or sows become pregnant after breeding (typically >85% of those inseminated). The expectation is that breeding will yield both a high percentage of pregnancies and also a large litter size (>11 piglets per litter).

Commercially raised females can exhibit a summertime decline in breeding efficiency (seasonal infertility) which is explained by the combined effect of heat stress and photoperiod. Typical signs of seasonal infertility are anestrus, weak or irregular expression of estrus, irregular estrous cycles, reduced farrowing rates, increased abortion rates, and depressed litter size. There are methods to mitigate heat stress on farm. For example, evaporative cooling systems will decrease the ambient temperature by 5–7 °C inside swine barns, depending on the outside temperature and relative humidity. These systems will reduce but not entirely eliminate the impact of seasonal infertility on the reproductive efficiency of swine farms.

Early Embryonic Development

Following ovulation, the sticky cumulus cells surrounding the oocytes assist adhesion and transport to the ampullary-isthmic junction (site of fertilization) of the oviduct through contraction of cilia lining the fimbria and ampulla luminal epithelium. Follicular growth and the release of estradiol stimulates oviductal contractions to move the oocytes to the site of fertilization. Estradiol stimulates a physical constriction of the isthmus lumen which restrains further movement until the uterus becomes receptive for embryo development. Fertilized ova undergo their first cleavage division approximately 24 h after fertilization. Cleavage continues with 4–8 cell embryos being rapidly transported into the uterine horns following progesterone induced relaxation and widening of the isthmus luminal diameter (Fig. 3). The embryos continue to divide near the tips of the uterine horns, developing into morula by Day 5 of gestation. The loose outer cells of the morula undergo compaction which is defined as the formation of tight cellular junctions. Polarization of the outer trophoblast allows sodium pumps located on the basal cell border to transport fluid into the center to form the blastocoel. The presence of the blastocoel is the defining characteristic of the blastocyst embryo which is found on Day 6–7 of gestation. Blastocysts continue to grow within the zona pellucida until production of enzymes from both the uterus and blastocyst and the physical expansion and contraction of the blastocyst stimulate hatching; the process through which the embryo breaks through the surrounding zona pellucida. Hatching occurs on Day 8 of gestation (Fig. 3).

From Days 8–12 of gestation, blastocysts begin to migrate down and between the uterine horns to equidistantly space themselves throughout uterus. Early uterine migration of blastocysts from the tip of the uterine horns is stimulated by blastocyst synthesis of prostaglandins that induce the release of histamine from the endometrium to stimulate local myometrial contractions. The spherical conceptuses continue to grow, migrate and complete spacing within the uterine horns through the production of estrogens (Fig. 4(A)). Conceptus migration and trophoblast expansion is essential because the pig has both a local and systemic pathway for PGF_{2α}-induced luteolysis (CL regression) which would reduce progesterone and terminate the pregnancy. The pig requires at least two conceptuses in each uterine horn to prevent luteolysis and maintain pregnancy.

The spherical conceptuses (Fig. 4(A)) steadily grow and increase in diameter from Day 10 (2–5 mm diameter) to 12 (8–10 mm diameter) of gestation. Once reaching an approximate 10 mm spherical diameter, conceptuses undergo a rapid transition in morphology to a thin filamentous tread-like structure measuring ~100 mm in length (Fig. 4(B)). The rapid morphological change during conceptus elongation occurs within approximately 1 h and results from massive cellular remodeling and movement rather than cellular growth and proliferation. Pig conceptuses synthesize a unique form of interleukin-1β (IL1B2) that is involved in regulating the rapid elongation of the conceptus. Gene edited *IL1B2* null embryos do not elongate. IL1B2 is a proinflammatory cytokine that stimulates a localized increase in blood flow to the uterus and regulates many endometrial responses to stimulate implantation and the maternal immune system.

Conceptus elongation provides the placental surface area for nutrient uptake that is essential for continued embryonic and fetal development to term. The pig endometrial surface is not a flat, smooth surface but has a substantial amount of primary and secondary folding (Fig. 4(C)). Conceptuses follow the folds and attach along the mesometrial border of the uterine horns.

Establishment of Pregnancy

Rapid conceptus elongation not only provides the surface area for later placental development and growth, but provides the mechanism to deliver conceptus estrogen (maternal recognition signal) across the endometrium to block luteolysis and maintain pregnancy. Two periods of conceptus estrogen production and release are involved in maintaining the CL throughout pregnancy in the pig. Conceptuses release estrogen during the process of elongation on Day 12 of gestation. This short pulse of estrogen production (1–2 days) extends the lifespan of the CL to 25–30 days. Although conceptus elongation normally occurs between Day 11–12, the window for elongation and uterine estrogen stimulation for establishment of pregnancy in the pig extends from Day 11–14 of gestation. A second sustained release of estrogen occurs during period of attachment and placental formation from Day 16–25 of gestation. The short (Day 12) and prolonged (Day 16–25) release of estrogen is essential for CL maintenance to term. Treatment

Fig. 4 Conceptus development from Day 11–12 of gestation. (A) Spherical conceptus (5 mm diameter) on Day 11 of gestation. (B) Elongated conceptus (100 mm) on Day 12 of gestation. (C) Segment of uterine horn demonstrating the multiple folding of the endometrium during placentation in the pig.

of cyclic gilts or sows with estrogen or environmental exposure to estrogenic compounds such as aflatoxins induces pseudopregnancy (extended lifespan of CL without conceptuses present) which can range from 28 to 110 days.

Conceptus secreted estrogens do not function to prevent luteolysis through inhibition of endometrial $\text{PGF}_{2\alpha}$ synthesis and release as occurs in a number of large farm animal species. In the pregnant pig, estrogen alters endometrial $\text{PGF}_{2\alpha}$ movement to redirect the $\text{PGF}_{2\alpha}$ away from the CL. The $\text{PGF}_{2\alpha}$ is sequestered into the uterine lumen and metabolized rather than being transported into the uterine capillaries to induce luteolysis as occurs during the estrous cycle. Pig conceptuses secrete PGE which also assists in sequestering $\text{PGF}_{2\alpha}$ into the uterine lumen and stimulates CL progesterone production and maintenance during early gestation.

Placental Attachment and Development

Evenly spaced, elongated conceptuses do not overlap and developing placenta do not fuse together during gestation. The conceptuses continue to grow and expand throughout the uterine horns growing from 100 mm to 500 mm length from Day 15–30 of gestation. The placenta will continue to grow reaching lengths of approximately 800–1000 mm by Day 70 of gestation. The pig has a noninvasive, epitheliochorial type of placentation which the chorion attaches to the surface epithelium along the folds of endometrium (Fig. 5(A)). The multiple primary and secondary folds of the endometrial lining allow the meter-long diffuse placenta (Fig. 5(B)) of each fetus to occupy a uterine area approximately one-third of its length (Fig. 5(A)). The endometrium of the pig contains thousands of uterine glands (Fig. 5(B)) to supply the nutrients needed for continued development to term. With regression of the yolk sac on Day 15 of gestation, complete attachment of the chorion to the endometrial surface epithelium occurs through expansion of the allantois from the hindgut of the developing embryo on Day 15. The fluid filled allantois expands throughout the chorion reaching a volume of 200–300 mL by Day 30 of gestation. Fluid in the allantois declines from Day 32–45 but a second increase in volume to 300–400 mL occurs and peaks on approximately Day 60 of gestation. The allantoic fluid declines from its peak volume on Day 60 to approximately 50–80 mL on Day 100 of gestation. The allantois serves as a reservoir for nutrients (proteins, amino acids, carbohydrates and ions) absorbed from the uterine glands by the overlying chorionic areola (Fig. 5(B)). The allantois may not expand to the extreme ends of the chorion when tips of placental membrane of individual fetuses make contact and ends fold over each other. The lack of placental blood supply from the allantois to the tip of the chorion results in the formation of brownish necrotic tips (Fig. 6). Placental length (800–1000 mm) and weight (200–250 g) of pigs continue to increase until approximately 70 days of gestation where it plateaus until parturition at 114–117 days of gestation.

Endocrinology of Pregnancy and Parturition

Corpora lutea do not regress during pregnancy because the conceptus prevents the secretion of $\text{PGF}_{2\alpha}$ into the uterine vasculature. There is a slight decline in circulating progesterone concentrations after Day 14 until term. The decline in circulating progesterone is explained by the steroid metabolism by the uterus and conceptus during pregnancy. Maintenance of circulating progesterone concentrations throughout gestation is totally dependent on the CL. Regression of the CL during pregnancy leads to abortion of the pregnancy.

Circulating concentrations of unconjugated and conjugated estrogens such as estrone sulfate increase from Day 16 to peak levels between Day 23 and 30 of gestation. The circulating concentrations then decline to low levels by Day 45 before slowly increasing to attain a second peak on the day before parturition. The fetoplacental unit is the primary source of circulating estrogen during pregnancy. Increases in estrogen follow the steroidogenic activity of the pig placenta and change in placental allantoic volume throughout gestation.

Parturition occurs on Day 114–117 of gestation in the pig. The release of glucocorticoids from the maturing fetal adrenal is associated with the initiation of parturition in the pig. The glucocorticoids stimulate the release of $\text{PGF}_{2\alpha}$ from the endometrium which in turn causes a rapid decline in circulating progesterone concentrations 1–2 day before parturition. There is the release of prolactin from the anterior pituitary and relaxin from the CL at this time as well. The release of prolactin stimulates mammary growth and lactogenesis. Along with relaxin, placental estrogen softens and dilates the cervix. The $\text{PGF}_{2\alpha}$ stimulates oxytocin release that increases myometrial activity that is essential for delivery of the piglets through the softened cervical canal. Sows can be induced

Fig. 6 Pregnant uterus (A) and fetal/placenta (B) collected on Day 60 of gestation.

to farrow after 110 of gestation. Before this time, induction of parturition results in a high percentage of stillborn piglets. Administration of exogenous $\text{PGF}_{2\alpha}$ (Lutalyse®, Zoetis Animal Health, Parsippany, New Jersey, United States) is an effective method to induce parturition after day 110. Delivery typically occurs within 2 days after treatment.

Sows are moved into farrowing rooms that are equipped with specially designed “farrowing crates” a few days before expected farrowing. The farrowing crates are designed to minimize the number of piglets that are crushed by the sow when she lays down. Farrowing in the sow typically occurs over a 2–5 h period. A typical interval between the delivery of each individual piglet is 10–15 min. Piglets are delivered randomly between the uterine horns. A typical delivery involves live born pigs, stillborn pigs, and mummies. Mummified pigs are brown in color and died at some time during gestation after there was skeletal development. Stillborn pigs appear completely normal but are dead at birth. Risk of stillbirth is greater for piglets born late in the farrowing process, for sows farrowing large litters, and for piglets born >20 min after the last piglet. If piglets fail to be delivered on time then it may indicate that there is a piglet lodged within the birth canal (dystocia). If this occurs then the piglet is removed manually (gloved hand passed through the cervix and into the uterus) by the person monitoring the sow at farrowing. Oxytocin can be administered to sows that fail to deliver piglets on time if there appears to be weak myometrial activity and there is no blockage within the uterus. The placenta are passed within 4 h of the delivery of the last piglet.

Lactation

The increase in prolactin, glucocorticoids, growth hormone, and relaxin during the days prior to parturition stimulates lactogenesis in the pig. Milk let down occurs following oxytocin release when piglets suckle. Piglets nurse as a group when allowed to suckle by the sow. The group nursing ensures that milk from all of the teats is consumed at the same time. Nursing interval during early

lactation is less than 1 h but this interval increases over time. Milk production in the sow increases during the third and fourth weeks of lactation.

Greater than 90% of live born pigs should survive until weaning. A common cause of death before weaning is crushing where the mother accidentally lays on top of a piglet and kills it. Runt piglets (extremely small piglets at birth) may also die before weaning because they are either crushed or fail to compete for milk. Piglets are typically cross-fostered at one to two days after farrowing by moving piglets from a sow with a large litter to a sow with a small litter. Cross-fostering is most-successful for sows farrowing within 1 or 2 days of one another.

Most sows are weaned at approximately 21 days (3 week) of lactation. Sows rarely come into estrus while they are lactating because pulsative LH release is suppressed by suckling. The development of large estrogenic ovarian follicles depends on LH and therefore the ovary has only small follicles when the sow is lactating. After weaning, however, there is a rapid increase in LH pulsatility that initiates the development of preovulatory follicles on the ovary.

Sows are moved out of farrowing crates into breeding and gestation barns immediately after weaning. Most sows will be in estrus within 3–7 days after weaning and are inseminated at that time. The endocrine and follicular changes after weaning are very similar to what was previously described for proestrus. Some sows do not return to estrus after weaning. These sows may be cystic (have large non-ovulatory follicular cysts on the ovary), may have ovulated during lactation (relatively rare) or may be anestrus (fail to develop follicles after weaning). There are no effective treatments for follicular cysts in the sow. Sows that are anestrus can be treated with P.G. 600 to induce estrus and then can be AI.

Sows remain in the herd until they either become subfertile (reduction in litter size or farrowing rate), become injured, or experience skeletal problems generally associated with feet and legs. A sow will typically be productive for 3–4 parities. The production cycle for a sow is approximately 142 days (gestation (114 days)+lactation (21 days)+return to estrus (7 days); assumes 100% efficiency). A sow, therefore, can farrow approximately 2.5 litters per years if she is healthy and highly fertile. If she weans 12 piglets per litter then 30 piglets per sow per year are produced. This level of productivity is achieved by approximately 10% of sows today. A more typical target for swine farms is 25 piglets weaned per sow per year.

Beef Cattle

Introduction

Beef cattle breeds are mono-ovulatory and polyestrous in nature and tend to have a defined estrous cycle length of approximately 21 days. Female reproduction begins when a beef heifer begins to cycle on a regular basis and normally coincides with the heifer reaching 50% of its adult weight at approximately 12–15 months of age. The estrous cycle is regulated in a similar manner to other mono-ovulatory species with the preparation of the uterus for successful pregnancy irrespective of whether or not an embryo is present. The embryo undergoes a period of rapid elongation of the trophectoderm cells, and maternal recognition of pregnancy is required in order for the corpus luteum (generated by restructuring of the cells from the ovulated follicle) and progesterone concentrations in circulation to be maintained. Placental formation in beef cattle is cotyledonary in nature and quite superficial with pregnancy lasting between 279–287 days depending on breed and sex of the foetus. Parturition is similar as in dairy cattle, but beef cattle do not experience the post-partum negative energy balance that dairy cows do and have comparative ease to become pregnant again. Specialist breeds of beef cattle are adapted to adverse conditions, e.g., tropical climates, which have led to some interesting reproductive functions. These comparative differences in female beef cattle reproduction will be explored in greater depth in the sections below (see [Table 1](#) for a summary).

Development and Puberty

Puberty is defined as the time at which estrus, accompanied by the ovulation of a dominant follicle, occurs. Reaching puberty, i.e., estrus and ovulation, in beef heifers is dependent on weight gain but occurs on average around 13–15 months of age. The optimum age at which beef cattle should first calf is 24 months of age. In order for this to occur, beef heifers should be inseminated at 15 months of age and should have been cycling prior to this. In general beef cattle hit puberty once they have reached 50% of their mature size (300–325 kg) and so the timing of puberty is dependent on the nutritional plane that the animal is on. Moreover, initiation of ovulation can also be affected by breed of cattle with faster growing breeds such as Charolais reaching puberty at a later time than slower growing breeds such as Angus and Hereford. The presence of a bull can also hasten puberty onset, likely through a pheromone response, though this has yet to be proven conclusively.

The Estrous Cycle and Ovarian Follicle Development

The role of the estrous cycle of beef cattle (typically lasting between 18–24 days in duration) is to ensure a cyclical pattern of ovarian activity that will culminate in the ovulation and successful fertilisation of a high-quality oocyte, allowing development of the embryo in a reproductive tract that has been hormonally primed to drive successful early pregnancy. Within each cycle there are two distinct phases, the luteal phase (14–18 days in duration) and the follicular phase (4–6 days) which, in beef cattle, are predominantly made up of three waves of follicle growth. These waves of follicle growth are initiated when a cohort of follicles is recruited from the ovarian follicle pool, begin to increase in diameter, and become more estrogenic. The fate of the dominant follicle is dependent on the stage of the estrous cycle during which it grows and this is regulated by a series of positive and negative feedback mechanisms acting through the hypothalamus, pituitary and gonad axis (HPG-axis) ([Forde et al., 2011](#)).

Table 1 Comparison of major reproductive events of female cattle compared to different model and domestic species

	<i>Cattle (Bovine)</i>	<i>Sheep (Ovine)</i>	<i>Pig (Porcine)</i>	<i>Mouse (Murine)</i>	<i>Human</i>
Ovulation type	Spontaneous	Seasonal	Continual	Spontaneous	Spontaneous
Ovulation number	Mono-ovulatory	Mono-ovulatory (mainly)	Poly-ovulatory	Poly-ovulatory	Mono-ovulatory
Embryonic genome activation	8–16 cell stage	8–16 cell stage	4–8 cell stage	2-cell stage	4–8 cell stage
Completion of X-Chromosome inactivation	Post-blastocyst	Possibly blastocyst	Post-blastocyst	Blastocyst	Blastocyst
Elongation rate	Rapid	Rapid	Extremely rapid	N/A	N/A
Pregnancy recognition signal	Bovine Interferon Tau	Ovine Interferon Tau	Estrogens	Prolactin	Human chorionic gonadotrophin
Placentation	Cotyledonary	Cotyledonary	Diffuse	Discoid	Discoid
	Synepitheliochorial	Synepitheliochorial	Epitheliochorial	Haemochorial	Haemochorial
Duration of gestation (Days)	279–292	142–152	114	21	280

Gonadotrophin releasing hormone (GnRH), a low molecular weight neuropeptide produced in the hypothalamus, regulates the estrous cycle by controlling the secretion of the gonadotrophins luteinising hormone (LH) and follicle stimulating hormone (FSH) from the anterior pituitary gland. GnRH is released in a pulsatile manner via the hypophyseal portal blood system to prevent desensitisation of its receptor on the gonadotroph cells of the anterior pituitary. The release of LH and FSH is mediated by the binding of GnRH to its G-protein coupled receptor on the cell surface of the gonadotrophs. This stimulates intracellular calcium release and activation of the mitogen-activated protein kinase (MAPK) signalling pathway culminating in the release of stored LH and/or FSH depending on the stage of the estrous cycle. During the follicular phase the pre-ovulatory GnRH surge leads to high amplitude and frequency of LH pulse release as there are negligible amounts of progesterone in circulation. This allows for the ovulation of the dominant follicle. Following ovulation LH is responsible for rearranging the granulosa and theca cells of the ovulated follicle into the corpus luteum and thus progesterone concentrations in circulation begin to increase and the estrous cycle enters the luteal phase. At all stages during the estrous cycle a transient rise in FSH is responsible for the recruitment of the cohort of follicles from the ovarian pool. These follicles in a given cohort undergo distinct stages of growth with (1) emergence of the cohort of follicles (preceded by increased FSH), (2) selection of the dominant follicle for that cohort, and (3) follicle dominance followed by either atresia (during the luteal phase) or ovulation (during the follicular phase) of the dominant follicle. Each of these stages are characterised by distinct events with emergence of a follicle wave defined as the growth of a cohort of follicles ≥ 5 mm in diameter and coincides with a transient increase in FSH secretion. Selection of one dominant follicle in beef cattle occurs following a decline in FSH concentrations in circulation and all other follicles in that cohort undergo atresia via programmed cell death by apoptosis. During the dominance stage of the wave, the single selected follicle suppresses any remaining estrogen active follicles in that cohort. Whether or not that dominant follicle ovulated is dependent on whether or not it is in the luteal phase (cannot ovulate) or the follicular phase (can ovulate). As beef cattle have predominantly three waves of follicle growth per cycle, the dominant follicle from two out of these three waves of growth will never be destined to ovulate.

Role of the Dominant Follicle in Regulating the Estrus Cycle

Both FSH and LH play a role in the growth and development of ovarian follicles by binding to their respective receptors. FSHR is expressed during the emergence stage of follicle development, allowing the follicles in a cohort to grow. Once the dominant follicle is selected it produces increased quantities of estradiol and inhibin which suppresses FSH release from the anterior pituitary. The dominant follicle acquires LHR which allows it to continue to grow under a low FSH but high LH environment. If this occurs during the luteal phase, i.e., when progesterone concentrations are high, then the dominant follicle cannot ovulate, will regress and undergo cell death. This results in the removal of estradiol and inhibin from circulation, allowing another transient rise in FSH and the emergence of another cohort of follicles.

One of the hallmarks of a healthy follicle is the production of estradiol, which is detectable in the follicular fluid and is responsible for regulation of the estrus cycle as well as the display of estrus behaviour. Most follicles in a cohort at the emergence stage are estrogen active although some studies in beef cattle have shown that there are higher concentrations of estradiol in the dominant follicle prior to detectable differences in the diameter of the dominant follicle. Estradiol production occurs in a two-step manner with the production of androgens by the vascularised theca cells of the follicle and subsequent aromatisation of these androgens to estradiol in the avascular granulosa cells. The binding of LH to its receptor in the theca cells stimulated the conversion of cholesterol to testosterone via 17α -hydroxylase. Following diffusion of testosterone into the granulosa cells it is aromatised to estradiol via P450_{aromatase} (CYP19A) and estradiol is released into the follicular fluid. Not only does estradiol have a local effect on the follicle but is also involved in systemic regulation of the estrous cycle. The production of estradiol by the pre-ovulatory dominant follicle is sufficient to induce a surge of GnRH release from the hypothalamus resulting in an LH surge of sufficient pulse frequency as to stimulate final maturation of the follicle. This increases estradiol concentrations in follicular fluid, resulting in positive feedback to GnRH, LH, and FSH culminating in ovulation and estrous behaviour display. The display of estrus behaviour in beef heifers is between 12–14 h whereas beef cows, kept indoors, tends to display estrus behaviour for less time (8.5 h). As with dairy cattle, the duration and intensity of estrous display are affected by environmental factors including surface type, size of the group and bull presence. But there is no evidence that estrus behaviour follows any distinct diurnal pattern.

Two additional families of genes and proteins can indirectly impact the feedback system and display of estrus behaviour in beef cattle. These are the insulin-like growth factor (IGF) family and the transforming growth factor Beta superfamily of genes, which alters estradiol production by the ovarian follicle. IGF-1 stimulates estradiol production by follicles, but its bioavailability is strictly controlled by the IGF binding proteins. The composition of IGF binding proteins in the follicular fluid of a given follicle can alter the follicle's ability to drive estradiol production and may affect the expression of estrus behaviour. Similarly, activin, follistatin and inhibin can inhibit its production (Roche, 1996). The careful balance between these members of the TGF Beta superfamily can modify estradiol production with consequences for estrous behaviour.

The Corpus Luteum

Unlike dogs and cats, the CL of beef cattle has a finite life-span and requires an inhibition of the luteolytic mechanism to maintain high concentrations of P4 in circulation that will support and maintain pregnancy. Throughout the luteal phase of the estrous cycle,

progesterone secretions from the corpus luteum are sufficient to suppress LH amplitude and pulse frequency as to inhibit ovulation of the dominant follicle. In the non-pregnant state, regression of the corpus luteum is similar to other ruminants and is a result of the actions of endometrial-derived prostaglandin $F_{2\alpha}$ (PGF_{2A}), acting in an extra-uterine manner and stimulating CL regression. The CL produces oxytocin which binds to its cognate receptor on the endometrial epithelium and stimulates production of PGF_{2A} in a positive feedback loop. If there is an appropriately developed conceptus present, producing sufficient quantities of the pregnancy recognition signal Interferon Tau, then oxytocin receptor up-regulation in the endometrial epithelial cells is inhibited and PGF_{2A} production and release are suppressed.

Ovarian Reserve and Oocyte Growth

The ovarian follicle reserve in beef cattle is likely laid down during development with the oocyte housed in a primordial follicle with one layer of granulosa cells surrounding it. The reproductive lifespan of female beef cattle is dependent on the ovarian reserve and different subspecies had different ovarian reserves. For example, the subspecies *Bos taurus indicus* has a significantly larger ovarian reserve as well as numbers of follicles per cohort, compared to their *Bos taurus taurus* counterparts. This phenomenon has been demonstrated through ovarian scanning as well as measurement of anti-mullarian hormone (AMH) in blood, which is a proxy marker for ovarian reserve. The majority of oocytes reside in the ovarian reserve in an immature state and as such go through a 90-day period of growth where they can acquire developmental competency. This process involved both nuclear and cytoplasmic maturation of the oocyte in order for it to acquire sufficient mRNAs and proteins to drive embryo development up to embryonic genome activation (EGA).

Pre-Implantation Embryo Development

If there is successful fertilisation of the oocyte in the oviduct by a sperm, this structure is referred to as the zygote. This consists of a single cell with the diploid number of chromosomes arising from the fusion of the two haploid gametes. This is distinct to the formation of a parthenode which can be artificially induced in beef cattle embryos *in vitro* by chemical activation of the oocyte without fertilisation. The first distinctive morphological stage of embryo development is cleavage formation i.e. mitotic division of the cell (s) within the embryo to produce more cells (known as blastomeres) without an overall increase in the size of the embryo. The time to first cleavage in beef cattle has been used as a marker of developmental potential and during this stage the embryo drives these cell cycle divisions by using maternal-derived and stored transcripts and proteins. This is then followed by EGA, whereby the embryonic genome begins the process of active transcription and translation of genes and proteins to drive embryo development. The process of EGA is species specific but occurs in bovine embryos (both beef and dairy cattle) between the 8-cell and 16-cell stage of development. More recently there has been the identification of genes expressed at the 4-cell stage of development that are proposed to be involved in driving EGA (Li *et al.*, 2013). This discovery was made possible by exploiting the subspecies differences between *Bos taurus* and *Bos taurus indicus* whereby *indicus* sperm was used to fertilise *taurus* oocytes. Taking advantage of single polymorphism differences between these two subspecies and next generation sequencing, the authors could identify what transcripts were generated from the embryo rather than those that were maternally-derived. The authors identified the genes upstream binding transcription factor, RNA polymerase I-like 1 (UBTF1), heterogeneous nuclear ribonucleoprotein A2/B (HNRNPA2B1), Krüppel-like factor 17 (KLF17), and Kelch-like family member 28 (KLHL28) as well as gene ontologies involved in RNA processing and transport as novel genes involved in driving the EGA process in bovine embryos (Graf *et al.*, 2014).

A second key event in early embryo development is the formation of distinct cell lineages from the blastomeres that go on to form components of the embryo proper (inner cell mass) and the outer cell mass that forms the extraembryonic membranes. This is a process that is different in bovine embryos to that which occurs in mice. There are specific genes associated with the trophectoderm cell lineage including H+/K+ transporting non-gastric alpha2 subunit (ATP12A), caudal type homeobox 2 (CDX2), disabled homolog 2 (DAB2), Interferon Tau (IFNT), ATPase keratin 8 (KRT8), and transcription factor AP-2 alpha (TFAP2A). While markers for the epiblast include Nanog homeobox (NANOG), PR/SET domain 14 (PRDM14), POU class 5 homeobox 1 (POU5F1) and teratocarcinoma-derived growth factor 1 (TDGF1), GATA binding protein 6 (GATA6) and goosecoid homeobox (GSC) for the primitive endoderm. It is only when the formation of the morula stage of development (approximately day 4–5) that the distinction in cell lineage begins.

By the blastocyst stage of development, another key event that is still poorly understood in species other than mice, occurs; that is X-chromosome inactivation (XCI). In female embryos, there are two X chromosomes, while in male embryos there is one X and one Y chromosome. The Y chromosome in the male has a number of genes that are required to drive some of the male specific characteristics and include the sex determining region Y (SRY) gene. In female embryos, one of the X chromosomes must be inactivated in order for dosage compensation to occur. This process is regulated by the long non-coding RNA (lncRNA) X-inactive specific transcript (XIST). This lncRNA, along with other lncRNAs and proteins form the X-chromosome inactivation center (XIC) to allow for the inactivation of one of the X-chromosomes. However, unlike the process in mice which seems to be completed by the blastocyst stage of development, XCI in cattle is not complete at the blastocyst stage of development and seems to occur after the lineage specification into inner and outer cell mass but prior to gastrulation occurring.

In addition to EGA and XCI, another important process early embryo development in cattle is the differential methylation of different regions of the genome including areas hosting imprinted genes. Imprinting is a process whereby one allele of either the maternal or the paternal origin is silenced and differential methylation occurs at distinctive sites of the embryonic genome alter gene function. In the mouse model, where this has been most comprehensively studied, this process is stable throughout embryo development, however in cattle, the expression of the machinery and degree of methylation of these imprinted sites is very variable – particularly during the blastocyst stage of development.

One of the clear differences in early pregnancy morphology in beef cattle is the process of post hatching elongation. On approximately Day 8–10 the blastocyst hatches from the zona pellucida and under goes morphological changes from an ovoid conceptus on Day 13, to a tubular and then filamentous conceptus on days 14 and 15 respectively. This entire process of conceptus elongation is driven by secretions from the maternal uterine endometrium (see below) but the rate of conceptus elongation is also dependent on the embryo itself. The evidence for this is from multiple embryo transfer models where by *in vitro* produced bovine embryos are transferred into the same recipient and recovered on Day 14 display variation, even between embryos exposed to the same environment.

Interaction With the Female Tract for Early Pregnancy Success

In beef cattle, there is no strict requirement for the embryo to be exposed to the oviduct environment given it is possible to grow beef cattle embryos *in vitro* up to the blastocyst stage of development. These embryos can be transferred into synchronised beef heifer or cow recipients to result in successful pregnancy outcome. It is true however, that exposure to the oviduct environment, i.e., *in vivo* produced blastocysts, are of higher quality than their *in vitro* grown counterparts. This is likely due to exposure to the secretions from the oviduct epithelial cells which are not necessarily included as components of culture medium for embryos grown *in vitro*. In contrast, elongation of the conceptus must occur in the female tract as attempts to recapitulate this *in vitro* have not been successful. The elongation of the conceptus in cattle is governed by the post-ovulatory rise in concentration of the hormone progesterone. Progesterone in circulation acts indirectly on the embryo, by altering the transcriptome of the endometrium and subsequently the composition of the proteins, amino acids, ions, and other molecules that comprise the uterine luminal fluid. Elevated concentrations of progesterone advance the normal changes that occur throughout the estrous cycle while a delay in the post-ovulatory rise in progesterone causes a delay in the normal temporal changes that occur. What is clear from recent advances in omic technologies and utilizing these to understand early pregnancy events is that there is an optimum range of progesterone concentration in circulation that will drive successful elongation (through changes to the endometrial transcriptome and uterine fluid composition) (Forde and Lonergan, 2012). Data in the literature has shown that blanket progesterone supplementation treatments, either through vaginal pessaries or through stimulation of the endogenous and/or an accessory corpus luteum, do not necessarily result in improved pregnancy rates. Moreover, the changes that are observed in the endometrium/uterus that are modified with different concentrations of progesterone are not specific to external manipulation of progesterone as modifying the size of the ovulated dominant follicle (and subsequently the CL size) results in similar modifications to the endometrium (Fig. 1).

Fig. 1 Schematic diagram of the relationship between progesterone concentrations in circulation and mRNA expression values in the endometrium that are required to be down- and up-regulated in the post-hatching/elongation stage of conceptus development in order to establish uterine receptivity to implantation.

The rate of conceptus trophoblast elongation is correlated with IFNT production. Sufficient quantities of IFNT are required to signal the presence of the conceptus to the mother and maintain a functional CL and thus P4 concentrations in circulation. A significant number of studies have demonstrated there is a transcriptional response of the beef cow endometrium to the conceptus, predominantly on Day 16 (consistent with conceptus transfer data). There is a consistent transcriptomic signature which is amplified as day of pregnancy progresses from Day 15–20 and is predominantly due to the endometrial response to conceptus-derived IFNT. However, there are substantial changes to the endometrial transcriptome that are not a result of IFNT. Indeed, when IFNT was discovered there were a larger number of additional conceptus-derived proteins that were present/*de novo* synthesised by the conceptus but were not identified. More recent advances in proteomic technologies have identified additional conceptus-derived proteins that may modify endometrial function. An additional interesting phenomenon has been the discovery that conceptuses with different developmental competencies (*in vivo*, *in vitro*, and cloned embryos) elicit a different transcriptomic response in the endometrium indicating that the endometrium may modify its uterine receptivity to facilitate implantation to embryos with potentially different pregnancy outcomes.

The endometrium of beef cattle, unlike that of human or mice, does not undergo a decidualization response prior to implantation. What is clear however, is that there is some conservation in terms of gene expression patterns that are required for uterine receptivity to implantation, e.g., downregulation of the nuclear progesterone receptor from the luminal and glandular epithelium, regulation of secreted phosphor protein 1, increased production of IGF binding protein 1 and other proteins (Spencer *et al.*, 2016). This indicates that there are receptive and non-receptive uterine states in the endometrium of beef cattle.

Placental Development and Post-Partum Reproductive Issues

As mentioned above placental formation in cattle is very superficial and cotyledonary in nature. The main interaction sites are the aglandular caruncular regions of the endometrium which fuse with the foetal cotyledons to form the placentomes. The microscopic interactions between the maternal and foetal systems are termed synepitheliochorial in nature as binucleate cells from the foetus migrate and fuse with the epithelial cells of the endometrium to form syncytia which are responsible for the production of placental lactogen (Burton *et al.*, 2006). In beef cattle, 80% of the progesterone produced during pregnancy originates from the corpus luteum with only 20% derived from the placenta, demonstrating that the corpus luteum is required for pregnancy success for the majority of gestation.

Post-partum issues in cattle are distinct from those that occur in dairy cows, as they do not experience the post-partum negative energy balance complications and reproductive issues that dairy cows undergo in the demands for energy to drive milk production. However, post-partum there are some reproductive issues that are specific to beef cattle. Beef cattle are exposed to a transient rise in FSH 3–5 days after calving which results in resumption of recruitment and growth of a cohort of follicles 7–10 days post-partum. Ovulation of the resulting dominant follicles is dependent of LH pulsatile. Resumption of ovulation however, can be inhibited in beef cattle by severe body condition score loss or suckling stimulated inhibition which reduces GnRH release as consequently LH pulse amplitude and frequency.

Recent studies are demonstrating that beef cattle offspring may also be susceptible to postnatal consequences due to changes to the maternal environment. The developmental origins of health and disease (DOHaD) hypothesis, originating as the Barker hypothesis following observations of increased risk of death from cardiovascular disease in humans with low birth weight, has given rise to an entirely new field of study (covered in detail in other chapters in this book) (Pérez-Cerezales *et al.*, 2017). Recent studies looking at this phenomenon in beef cattle have reported some interesting findings. Restriction of dietary intake in the first three months of gestation in beef cattle results in offspring with decreased ovarian reserve and impairment of the cardiovascular system. More recently, culture of embryos from beef cattle donors for two days supplemented with Dickkopf-related protein one for two days had no impact on blastocyst development but did result in lower birth weight (Tribulo *et al.*, 2017). Collectively these data demonstrate that beef cattle can be susceptible to maternal environmental insults that may have transgenerational consequences.

Conclusion

Beef cattle have an interesting reproductive lifespan with some mechanisms that are conserved between closely related species, e.g., the sheep. However, there are some events that are unique to the bovine as a model, as indeed unique to beef cattle, which is an important consideration when trying to extrapolate reproductive processes between different species.

Glossary

Aglandular Without glands.

Anestrus Period in which female is not cycling. Ewes are anestrus when they are prepubertal ewe lambs, also during the non-breeding season or pregnancy.

Breeding season Period of time during the year in which sheep are capable of breeding. Regulated by light exposure do to photoperiod. Ovine breeding season is during reduced day length (i.e. fall-winter).

Caruncle Aglandular area of tissue lined by single layer of luminal epithelium, located on the uterine endometrium, projecting into the uterine lumen. Forms the maternal component of the placentome.

Conceptus Embryo and extraembryonic membranes.

Corpus luteum Post-ovulatory ovarian structure necessary for progesterone production.

Cotyledon Structure found on the placental membrane that provides the fetal component of the placentome.

Estrous cycle Female reproductive cycle between ovulatory periods. In sheep the estrous cycle is approximately 17 days long.

Estrus Period of female receptivity to mating as part of the estrous cycle.

Ewe Female ovine after at least one parturition.

Ewe lamb Female ovine between birth and first parturition.

Interferon tau Maternal recognition of pregnancy signal in the sheep, produced by the embryo.

Lamb Ovine offspring between birth and one year of age.

Luteolysis Destruction of the functional corpus luteum.

Maternal recognition of pregnancy A biochemical signal (interferon tau in sheep) produced by the conceptus for maintenance of pregnancy.

Oocyte Female gamete.

Ovulation Release of an oocyte from an ovarian follicle.

Parturition Expulsion of the fetus and placental membranes at the end of pregnancy.

Placentome Structure formed via interdigitation of maternal caruncle and fetal cotyledon. Site of high throughput nutrient exchange.

Puberty Time point of chronological and physiological maturity in which the animal is capable of releasing a gamete and becoming pregnant.

Ram Intact male ovine.

Sheep General term for all ages and sexes of ovine.

Synepithelialchorial placentation Minimally invasive type of placentation in which there is formation of a maternal-fetal syncytial layer at the placental-uterine interface.

Introduction

Sheep are the primary source of animal protein and clothing fiber for much of the world, ranking second to beef cattle in total numbers. Globally, they are a significant species as a greater number of individual sheep may be sustained on the same amount of forage as a single cow and sheep are frequently raised in arid climates with extreme variation in nutrient availability. The combination of sustainability on limited forage, minimal management requirements, and the potential protein and fiber production in such conditions makes them a favorable species for utilization in most of the world. As such, increased reproductive performance and efficiency is critically important. This article serves to review general aspects of female sheep reproduction.

Female Reproductive Tract Anatomy

In utero the reproductive tract of the ewe develops, anatomically, to a level that is very similar to its mature state. The reproductive tract is located ventrally to the rectum and is suspended within the body cavity by a structure known as the broad ligament. The broad ligament can be classified into subareas depending upon localization. The mesovarium supports the ovary, mesosalpinx the oviduct and mesometrium the uterus. At pregnancy the mesometrium will help to maintain the placement of the uterus despite the increased size and weight from the developing fetus.

The ovary is home to the female gametes that are at their maximal population just prior to birth. Unlike the ram, which begins a continuous production of gametes following puberty, the ewe is born with a finite supply of oocytes (ranging between 40,000 and 300,000 in total number) that are released at from meiotic arrest at puberty and are then capable of maturation, release and subsequent fertilization. The ewe ovary is an almond shaped structure in which the innermost component is termed the medulla and the external layer the cortex. The cortex is home to the gametes or oocytes. Oocytes are found within structures known as follicles. At birth groups or nests of primordial follicles can be detected throughout the cortex. As the animal matures, so do the follicles. After the female has reached the physiological maturity associated with puberty the follicular population will undergo a series of steps involved in maturation. The primordial follicle will progress through stages of development to become primary, secondary, tertiary and then ovulatory. As the ovulatory follicle is housed in the cortex, at ovulation, the oocyte will be released from the surface of the ovary.

The ovulated oocyte will be collected by the infundibulum, which is the anterior most portion of the oviduct. The infundibulum is lined by small finger like projections known as fimbriae that sweep over the cortex of the ovary in order to collect the oocyte and move it further into the oviduct. The next region of the oviduct encountered is the ampulla. Marked by the presence of cilia, the ampulla is also a secretory structure, which adds to the oviduct milieu that is necessary for successful fertilization. The ampulla transitions to the isthmus, a more muscular segment of the oviduct that at the time of mating will help to facilitate movement of spermatozoa to from the uterus toward the waiting oocyte. In the sheep fertilization takes place within the oviduct and the embryo begins the process of cellular division and development prior to entering the uterus. The sheep uterus has two distinctive horns that come together to form a single uterine body. The area of at which the uterine body separates into the two horns is known as the bifurcation.

The sheep uterus is clearly organized into a series of tissue layers, each serving a specific purpose. The exterior layer of the uterus or perimetrium is the outer most covering of the uterus. The next layers are smooth muscle termed the myometrium. The myometrium is comprised of layers of longitudinal and smooth muscle that are capable of coordinated muscle contraction, such as what is necessary for expulsion of the fetus at birth. Located between the myometrium and the lumen (central canal of the reproductive tract) is the endometrium. The uterine endometrium is made up of the uterine mucosa and submucosal layer, and as such it is a dynamic, secretory tissue that will ultimately provide a place for attachment and development of the embryo and extraembryonic membranes known as the placenta. The mucosa is lined by epithelial cells and the submucosa can be divided into two distinctive regions, the stratum compactum and stratum spongiosum stroma. The stroma of the adult ewe is populated with blood and lymphatic vessels as well as uterine glands.

While the majority of the reproductive anatomy of the ewe does not change after birth, the uterine endometrium undergoes a critical process: development of uterine glands ([Fig. 1](#)). The uterine submucosa or stroma of a mature ewe is densely populated with uterine glands. The secretory products of the uterine glands are necessary for pregnancy as they are the source of histotroph, a milieu of cytokines, lymphokines, growth factors, hormones, amino acids, glucose, fructose, vitamins, and additional substances that is an essential for early embryonic nutrition. However, at birth the endometrium of the ewe lamb lacks uterine glands. Immediately post-partum there is a series of invaginations of the uterine luminal epithelium that will extend as buds. They will continue to grow into the stroma and will undergo subsequent coiling and branching to give rise to the uterine glands. This developmental process is under strict endocrine control and inappropriate exposure to the steroid hormone progesterone during neonatal life can prevent gland formation. Of interest, this phenomenon has been utilized by researchers via the creation of the uterine gland knock out (UGKO) ewe, which has proven an exceptional tool for investigation of the role of uterine glands in pregnancy. The UGKO population is devoid of glands and incapable of maintaining a pregnancy ([Fig. 1](#)).

The surface of the ruminant endometrium is unique in that it contains discreet aglandular regions of tissue known as caruncles ([Fig. 1](#)). The endometrial surface of the sheep can contain upwards of 100 caruncles. In the ewe, the caruncles have a concave shape as they protrude from the surface of the endometrium. The caruncles are lined by luminal epithelium and are vascularized. They are fairly uniformly distributed throughout the uterine body and horns. They can range in diameter and those located closer to the tips of the uterine horns are smaller. During pregnancy, the caruncles will form the maternal component of structures known as placentomes.

Fig. 1 Representative photomicrographs of the uterus from cyclic (a,b), pregnant (c,d) and uterine gland knockout (UGKO) ewes (e,f) 14 days after mating, using a Masson's trichrome stain. This procedure stains nuclei black, cytoplasm and muscle fibers red and extracellular matrix (ECM) components blue. The left column (a,c) from normal ewes depicts intercaruncular endometrial regions and the right column (b,d) depicts caruncular endometrial area. No distinct caruncular or intercaruncular regions are distinguishable in uteri from UGKO ewes (e,f). L, luminal epithelium; G, glandular epithelium; SC, stratum compactum; SS, stratum spongiosum; M, myometrium; V, blood vessel. Scale bar represents 200 μ M. Reproduced from Gray, C.A., Burghardt, R.C., Johnson, G.A., Bazer, F.W., Spencer, T.E., 2002. Evidence that absence of endometrial gland secretions in uterine gland knockout ewes compromises conceptus survival and elongation. *Reproduction* 124, 289–300.

Placentomes are the sight of high throughput nutrient exchange between the uterus and developing fetus. They are formed by the interdigitation of maternal caruncular crypts and cotyledonary villi (**Fig. 2**). Cotyledons are located on the fetal chorion (outermost layer of the placenta) known as cotyledons and serve as the fetal component of the placentome. Placentomes are detectable as early as day 40 of pregnancy, becoming fully functional by day 60. The placentomes are the primary point of physical attachment between the uterus and placenta throughout pregnancy. At parturition (birth) the caruncles will separate from the

Fig. 2 Representative photomicrograph of a placentome using hematoxylin and eosin stain. The large panel depicts a complete cross section of a typical concave, A type placentome of the sheep. The maternal and fetal labels provide orientation, as maternal is adjacent to the uterine stroma and the fetal is proximal to the uterine lumen. The high magnification inset depicts the interdigitation of the caruncular crypt and cotyledonary villi, which are separated by a layer of syncytial epithelium. Fixation artifact space is also labeled. Scale bar represents 1 mm.

placental membranes and remain attached to the uterine endometrium. In the postpartum interval the caruncles will undergo necessary repair of tissue and vasculature in order to return to their original disposition.

The size and shape of placentomes can vary within and between animals. In sheep the placentomes can be classified by shape ranging from A-D type based upon the relative configuration of the caruncle to cotyledon. In an A type placentome the caruncle will maintain a concave position with the cotyledon being centrally attached. The caruncle will essentially surround the cotyledon, forming a nearly spherical structure with placental membranes exiting the apex of the placentome. Conversely, a D type placentome will be inverted in that the caruncle will have taken on a convex shape and the cotyledon will be surrounding it. This is the type of placentome characteristic of the cow, in that bovine caruncles are convex rather than concave in shape. Total mass of placentomes has been shown to correlate to fetal weight and pre-mating surgical removal of caruncles, which causes an overall reduction in placentome number and mass, will reduce fetal weight and can compromise pregnancy.

Immediately caudal to the uterus is the cervix. This is a fibrous structure that primarily functions as a protective barrier. In the sheep the cervix is identifiable by the series of annular rings that it possesses. These rings (typically 4–7) provide an initial barrier to foreign particles as well as spermatozoa as they create a tortuous pathway for spermatozoa to navigate. The cervix is a secretory organ whose products will vary dependent upon the endocrine cues provided. At the time of mating (i.e., estrus) the cervix will secrete mucins to help facilitate spermatozoa transport. If pregnancy is successful a more solid mucous barrier is formed to help protect the uterus from influx of foreign material. At parturition the cervix will dilate to enable passage of the fetus and placental membranes from the uterus to the vagina.

The vagina of the ewe is the most caudal interior region of the reproductive tract. At mating this is the receiving site for the male's penis and at parturition is part of the fetal birth canal. Resultantly the epithelium must protect against abrasions as well as introduction of foreign materials. The secretory activities of the vagina are also heavily influenced by endocrine control. As example, under influences of high estrogen (i.e., at estrus) the vagina becomes highly secretory, and can lead to discharge visible at the vulva. The vulva is the portion of the female reproductive tract visible from outside the body cavity. While not as prevalent a concern as it is in pigs, vulva structure can influence mating efficiency in sheep. A small or tipped vulva can make penetration by the ram more difficult thus potentially reducing fertilization.

Puberty and the Breeding Season

The chronological age at which sheep typically reach puberty is 5–12 months. Influencing factors include breed, environment, photoperiod and nutritional status. Physiologically, a lamb is considered pubertal when it is capable of producing gamete and

maintaining a pregnancy. Body size is one of the most visible external measures. Ewe lambs must meet a minimum threshold of frame size and body condition prior to initiation of puberty. An additional factor that impacts a lamb's entry into the breeding population is the photoperiod in which they were born.

Sheep are termed to be "short day" breeders, meaning that the decreased light-levels associated with shorter days will positively influence the hormonal control of gamete production in both the male and female. Resultantly most sheep have a breeding season that is inversely correlated with the amount of light they are exposed to. As the typical gestation length of a sheep is 147 days, an ewe that is bred in the fall will lamb in the early spring. Therefore those lambs will first be exposed to increasing photoperiod and will be growing during this time (i.e., the non-breeding season). Their body composition will be suitable so that when they are then exposed to the shorter days of breeding season they are more apt to undergo puberty and successfully mate. Conversely, lambs born in the summer and/or early fall will not have reached a sufficient body mass to be pubertal during their first exposure to decreased day length. Nor will they have experienced the pattern of increasing and then decreasing photoperiods, which are necessary to stimulate puberty in sheep. Resultantly, they will enter puberty at an older age and will not breed until the following short-day time period, thus making them less reproductively efficient than their peers.

The transition from an anestrus or pre-pubertal state to one of cyclicity requires a change in the ewes' endocrine profile. Specifically, within the ewe's brain the action of kisspeptin neurons will trigger an increased frequency of pulsatile release of gonadotropin releasing hormone (GnRH) and luteinizing hormone (LH). The change in endocrine release pattern will support ovarian function, including steroid hormone production and follicular maturation.

Behavioral signs of estrus are the most frequently utilized to determine a female is capable of breeding. However, those signs often accompany the second ovulation occurring during the transition from anestrus to estrus. When ewes enter the period of cyclicity either at puberty or the start of the breeding season, they frequently undergo a "silent ovulation" meaning that an oocyte is released from a dominant follicle without accompanying signs of estrus behavior. The hypothalamus requires progesterone priming in order to facilitate the endocrine cues necessary for such behavior. The corpus luteum (CL) formed from the silent ovulation will produce the progesterone necessary to feedback upon the hypothalamus to trigger initiation of estrus-like behavior in the subsequent cycle. The nuance of neuroendocrine control of cyclicity is one of the many challenges associated with determining the exact point at which a ewe enters puberty and/or the breeding season.

Cyclicity

The ewe typically has an estrous cycle (period of time between ovulations) that is approximately 17 days in length. The cycle is characterized by specific intervals of time that correspond to the presence of specific ovarian structures and endocrine profiles. During the period of estrus a female is receptive to mating. Behaviorally, she typically will stand to be mounted by the male, may mount other females and there may be discharge detectable from her vulva. During this time there is a dominant follicle present on the ovary that is producing quantities of estrogen capable of exerting positive feedback on the hypothalamus. At the end of estrus, estrogen levels will begin to decrease and there will be a surge in LH from the anterior pituitary that will trigger ovulation of the dominant follicle. The post-ovulatory follicle will then be termed a corpus hemorrhagicum (CH). The post estrus time period is metestrus and is the time of transition in which the remaining post-ovulatory follicular theca and granulosa cells give rise to the small and large luteal cells. These cells will comprise the corpus luteum (CL), which is the ovarian structure responsible for progesterone production. The CL is the dominant structure during diestrus and if the ewe were to become pregnant would remain intact throughout gestation. If the ewe does not become pregnant the CL will undergo a process of destruction known as luteolysis following exposure to prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) produced by the uterine endometrium. The regressed CL leaves an inactive structure resembling a pale scar, the corpus albicans (CA).

In the absence of an embryo, endometrial $PGF_{2\alpha}$ travels from the uterine vein to the ovarian artery via counter-current exchange and with a series of coordinated frequent, high amplitude pulses is capable of inducing apoptosis of the CL. In the non-pregnant ewe this will occur at the end of diestrus and will result in a decrease in progesterone production. The ewe will then enter proestrus and with it will have increasing levels of estrogen, follicle stimulating hormone (FSH) and LH, as there is a follicular pool that has been preparing for ovulation during the subsequent estrus period.

The development of follicles suitable for ovulation is frequently described as a wave like pattern. In sheep there are typically three to four follicular waves within an estrous cycle (Fig. 3). The last wave in a cycle is the wave that results in ovulation. The proceeding waves do have an increase in FSH and estrogen levels from the follicles that have matured prior to undergoing regression. Manipulation of the follicular waves remains a key area of research interest within all ruminants.

Embryonic Development and Implantation

Early embryonic loss is an important factor in livestock production and resultantly considerable effort has been extended to understand the process of embryo development and subsequent implantation into the uterus in an effort to mitigate such losses. Following successful fertilization the embryo undergoes a series of morphological and developmental changes within the oviduct prior to entering the uterus (Fig. 4). After the initial fusion of the male and female pronuclei to form a single celled zygote the embryo will cleave into two blastomeres. The blastomeres will continue to divide and the embryo will reach the morula stage of

Fig. 3 Schematic illustration of the growth of ovarian antral follicles emerging at 2–3 mm in diameter during the ewes' estrous cycle. The largest follicles that grow to an ostensibly ovulatory diameter of ≥ 5 mm before regression or ovulation emerge in an orderly succession throughout the 17-day interovulatory interval, giving typically 3 or 4 follicular waves. OV=ovulation. The approximate durations of the growing (G), static (S) and regressing (R) phases of the lifespan of the largest follicles of waves are shown in the upper chart area. Reproduced from Bartlewski, P.M., Baby, T.E., Giffin, J.L., 2011. Reproductive cycles in sheep. *Anim. Reprod. Sci.* 124, 259–268.

classification by day 6 of pregnancy. At this point in development, the embryo is moving from the oviduct to the uterine horn and will enter the uterus as a blastocyst. The blastocyst is the embryo after it has undergone the process of compaction, which yields a defined inner cell mass, blastocoel and trophoblast. Upon hatching from the zona pellucida on day 8 of gestation the blastocyst will expand to form a spherical shape and begin the process of maternal recognition of pregnancy. The sheep embryo produces a type 1 interferon known as Interferon tau (IFNT) that serves as the maternal recognition of pregnancy signal and as such prevents production of endometrial $\text{PGF}_{2\alpha}$ and subsequent loss of the CL.

The mononuclear trophoblast cells, which are located on the periphery of the embryo, will secrete IFNT. The actions of IFNT on the uterine endometrium include the downregulation of estrogen receptor alpha, which will prevent stimulation of oxytocin receptor gene transcription. Loss of available oxytocin receptors will preclude oxytocin from stimulating the pulsatile release of $\text{PGF}_{2\alpha}$ capable of lysing the CL. In addition to down-regulation of factors driving luteolysis, binding of IFNT to its endometrial receptors causes upregulation of a series of IFN-stimulated genes necessary for successful implantation (Table 1).

Occurring concomitantly with maternal recognition of pregnancy is a rapid morphological change in the development of the sheep embryo (Fig. 4). After blastocyst formation and hatching, the embryo will undergo a series of changes from gestational days 9–15, that will result in it taking on an ovoid, tubular and ultimately filamentous form (approximately 10–15 cm in length). Successful elongation and implantation is dependent upon multiple factors.

Fig. 4 (A) Oocytes fertilized in the oviduct enter the uterus at the morula stage, hatch from the zona pellucida as spherical blastocysts and then transition to large spherical, tubular and filamentous conceptuses (embryo and its extra-embryonic membranes) with interferon tau (IFNT), the pregnancy recognition signal, being secreted from mononuclear trophoblast cells between Days 10 and 21 of pregnancy. (B) Endometrial epithelia cease expressing receptors for progesterone (PGR) due to autoregulation by progesterone and IFNT silences expression of receptors for estradiol (ESR1) and oxytocin receptors (OXTR) to abrogate development of the mechanism for oxytocin-mediated pulsatile release of prostaglandin $F_{2\alpha}$ (PGF) which would otherwise cause regression of the corpus luteum and cessation of progesterone secretion. The endometrial stromal fibroblasts express PGR and secrete fibroblast growth factor 10 that regulates uterine epithelia cell function. With down-regulation of PGR in uterine epithelia the uterine luminal (LE) and superficial glandular (sGE) epithelia express genes that are either induced by progesterone (P4) or induced by P4 and further stimulated by IFNT. Further, IFNT induces expression of interferon regulatory factor 2 (IRF2) in uterine LE and sGE to silence expression of classical interferon stimulated genes and allow expression of a unique set of genes that promote conceptus growth and development. The endometrial glandular epithelial cells (GE) and stromal fibroblasts do not express IRF2 and, therefore, express classical interferon stimulated proteins. Collectively, molecules secreted by uterine epithelia or transported into the uterine lumen by uterine epithelia form histotroph required for conceptus development. (C) The ovine conceptus undergoes the adhesion cascade for implantation. Reproduced from Bazer, F.W., Song, G., Kim, J., *et al.*, 2012. Uterine biology in pigs and sheep. *J. Anim. Sci. Biotechnol.* 16:3 (1), 23.

Progesterone produced by the CL is necessary for conceptus elongation and implantation. Ovarian progesterone also induces expression of a variety of genes in the uterine endometrium (Table 1). The general classifications include those encoding transport of glucose, transport of amino acids, cell proliferation, migration, attachment, proteases and their inhibitors, and intracellular enzymes. Exposure to increased quantities of exogenous progesterone after ovulation will enhance conceptus elongation (Fig. 5).

Another key factor in conceptus growth and successful establishment of pregnancy in the peri-implantation period is the presence of the envelope protein of the endogenous Jaagsiekte sheep retrovirus (enJSRV). Unique to sheep, enJSRVs have integrated into the genome. Multiple copies of enJSRVs have been detected within the genome of domestic sheep. The enJSRV envelope protein has been deemed essential for appropriate cellular proliferation of the conceptus of the sheep, as its absence results in failed elongation leading to embryonic loss.

Among the hypothesized methods for communication between the developing conceptus and uterine endometrium of the sheep are exosomes or microvesicles. These structures are present in multiple tissues and body fluids including the uterine luminal fluid of the sheep as well as the endometrial epithelium. As they are membrane-covered nanovesicles (30–150 nm) that are capable of carrying genetic material such as mRNAs, they are potentially capable of exerting a great deal of influence on uterine gene expression as well as cellular function such as migration and elongation which is necessary for conceptus development and implantation in the sheep.

Data from Spencer, T.E., Forde, N., Lonergan, P., 2015. The role of progesterone and conceptus-derived factors in uterine biology during early pregnancy in ruminants. *J. Dairy Sci.* 99, 5941–5950.

Fig. 5 Effects of early exogenous progesterone treatment on blastocyst morphology on Days 9 and 12 of pregnancy. In study two ewes were treated daily with corn oil (CO) vehicle or progesterone (P4) from 36 h postmating. On Day 9, blastocyst diameter was greater ($P < 0.02$) for ewes receiving P4 ($636 \pm 64 \mu\text{m}$) than CO ($282 \pm 64 \mu\text{m}$). In study 1, ewes were treated daily with CO or P4 from 36 h postmating to D 12. Elongated and filamentous conceptuses were recovered from P4-treated ewes, while only spherical to early tubular blastocysts were recovered from CO-treated ewes. Bar = 400 μm . Modified from Satterfield, M.C., Bazer, F.W., Spencer, T.E., 2006. Progesterone regulation of preimplantation conceptus growth and galectin 15 (LGALS15) in the ovine uterus. *Biol. Reprod.* 75, 289–296.

The fully elongated sheep conceptus will adhere to the endometrial luminal epithelium of the uterine horn adjacent to the CL and begin the process of implantation. This process requires changes in relative uterine gene expression to signal down regulation of anti-adhesion molecules, and upregulation of adhesion molecules, as well upregulation of multiple IFN-stimulated genes. Successful implantation will continue to trigger changes in endometrial gene expression that will maintain production of histotroph, stimulate increased vascularization and angiogenesis within the endometrium and caruncles, as well as facilitate formation of syncytia necessary for successful placentation.

Placentation

Sheep have a synepithelialchorial type of placentation whereby the embryo does not invade into the uterine wall as it does in rodents or primates, but rather extends upon the uterine surface. In sheep the mononuclear trophoblast cells will form binucleate

cells that will interact with the luminal epithelium to form a syncytial layer. The intercaruncular endometrium and placenta maintain contact through a series of focal adhesions. These contact points are not as rigid as those found within the placentomes.

Subsequent to IFNT production by the trophoblast, the placenta continues to produce pregnancy specific proteins such as pregnancy associated glycoproteins (PAGs), pregnancy specific protein B (PSPB) as well as placental lactogen (oPL). The growing placenta is also a source of progesterone production. Interestingly, in the sheep the placenta produces sufficient quantities of progesterone after day 60 of pregnancy to maintain pregnancy without the contribution of the CL.

As pregnancy progresses there is a switch between histotrophic and hematotrophic nutrition in the sheep. In early pregnancy the intercaruncular areas of the pregnant uterus experiences a significant increase in capillary density, further facilitating the transfer of nutrients from the mother to the fetus through histotroph. Later in gestation, 85% of uterine blood flow to the uterus travels through developed placentomes, which are the primary locations for hematotrophic support of the developing fetus. Uterine blood flow increases by approximately three fold in the later half of gestation in the ewe. The initial increase in uterine blood flow is followed by an increase in placental mass, reaching its peak around day 90 of gestation. A secondary increase in flow occurs between days 120–140, coinciding with rapid fetal growth. Fetal and placental weights and uterine blood flow are highly correlative. Factors that alter fetal weight such as genotype, maternal nutrient intake, heat stress, altitude, and fecundity, result in parallel alterations in placental weight and uterine blood flow. Increased blood flow and placental mass help to facilitate the transfer of nutrients necessary to sustain the rapid fetal growth that is characteristic of the third trimester of pregnancy in the sheep.

Parturition

Parturition is an intricate process requiring interaction and endocrine regulation by the ewe and lamb. As pregnancy progresses the endocrine profile of the fetus begins to change. There is a stimulation of the hypothalamic-pituitary-adrenal axis of the fetus. This is responsible for an increased production of adrenocorticotropin hormone (ACTH) and adrenal cortisol, which are necessary for initiation of parturition.

Additionally, late in gestation placental hormone production begins to shift. There is an increase in production of prostaglandin E₂ (PGE₂) that occurs after day 100 of gestation. The PGE₂ can further stimulate the production of fetal ACTH and cortisol as well as initiating matrix breakdown necessary for cervical ripening. As parturition becomes eminent fetal cortisol production continues and there is a decrease in progesterone and corresponding increase in estrogen. Elevated estrogen increases secretions of the cervix and vagina to facilitate lubrications of the reproductive tract for delivery, and also serves to upregulate oxytocin receptors within the uterine myometrium. Binding of oxytocin to its receptors will facilitate the coordinated muscle contraction necessary for expulsion of the fetus and placental membranes.

Parturition can be complicated by the presence of multiple fetuses. Ideally lambs will present for delivery individually, with their head positioned between their forelimbs. Each lamb possesses an individual placenta and membranes must be expelled after parturition. The uterus will begin the process of involution allowing for repair and a return to its non-pregnant state. The udder of the ewe has two teats enabling her to nurse twins effectively. In cases in which there are greater than two lambs per ewe supplementation is frequently necessary. Lactation is beyond the scope of this article.

Influence of Maternal Nutrition on Reproductive Processes

Maternal nutrition impacts ovulation, fertilization, and fetal development. The process of increasing maternal nutritional intake through administration of a high energy feedstuff in the month prior to breeding is known as flushing. In ewes suffering from diminished body condition this process has the potential to increase ovulation and fertilization rates. Maternal nutrition is also critically important during pregnancy. Ewes receiving less than the National Research Council (NRC) recommendations are at risk for compromised pregnancies as maternal nutrition during pregnancy impacts fetal growth. Insufficient nutrient availability can cause restricted fetal growth resulting in lambs that are small for gestational age. Lamb production, the main source of income for sheep flocks worldwide, is dependent on the birth of viable lambs with appropriate birth weight, which is a key determinate of neonatal survival.

The placenta plays a key role in responding to maternal nutritional constraints to facilitate fetal growth. As pregnancy depends upon cross-talk between the maternal and the fetal compartments via the placenta an insufficient supply of nutrients from the mother, leads to compensatory adaptations to enhance size, architecture and function of the placenta allow demands for fetal-placental growth to be met. Placental gene expression influencing nutrient transport is altered in an effort to promote fetal growth as a means to enhance lamb viability.

Maternal metabolic stress resulting in diminished birth weight also translates into poor post-natal performance of lambs. Growth restricted and/or small birth weight lambs demonstrate slower growth rates, decreased feed intake, and either reduced adult carcass merit or reproductive performance when compared to their counterparts from well-fed dams.

Poor maintenance of a ewe's body condition during pregnancy can also lead to post-partum difficulties including decreased lactation and a slower return to cyclicity. While sheep are adaptable to a wide range of forage quality and availability, it is necessary to consider nutritional needs in order to facilitate reproductive success and offspring viability.

Conclusion

The sheep is a valuable commodity in terms of food and fiber production as well as serving as an interesting and useful model for research in reproduction. The understanding of basic sheep reproduction and how it is impacted by factors such as genetics, environment, and developmental programming, will enable development of more optimal management tools that will allow for increased reproductive performance and profitability.

Introduction

The reproductive biology of the mare features a number of enigmatic events that presumably evolved to facilitate the birth, at yearly intervals, of a single precocious neonate able to stand, suckle and run within hours of delivery. Given that gestation lasts 11 months, to produce a foal annually at a time when grass is abundant a mare needs to conceive in late spring to early summer, and within a month of any previous foaling. Equine pregnancy incorporates a number of unusual features, including the selective descent of developing embryos into the uterus, and an unusually long period of intrauterine conceptus migration that is essential for successful ‘maternal recognition of pregnancy’. In fact, the preimplantation period as a whole is unusually long, with the chorioallantois only finally establishing a stable villous attachment to the endometrium at day 40, by when it must support a fetus with precursors of all its major organs. Intriguingly, definitive non-invasive placentation is preceded by endometrial invasion by a specialized band of trophoblast cells to form temporary endocrine structures known as the endometrial cups. Once placental interdigitation has been initiated, to meet the nutritional and respiratory needs of a fetus that will weigh around 10% of maternal body weight at term (e.g., 80 kg in a draft breed), the surface area for exchange is maximized by extensive branching of the chorioallantoic villi to form the ‘microcotyledons’, accompanied by expansion of the chorioallantoic sac to line the entire uterine lumen. For the first 3 months of gestation, pregnancy maintenance depends on ovarian progesterone; thereafter the placenta assumes the (pro)gestagenic support role. Moreover, during mid-gestation the placenta cooperates with the tremendously enlarged fetal gonads to produce large quantities of unique estrogens that promote uterine blood flow and help prepare the uterus for parturition.

Reproductive Seasonality

Mares are long-day seasonally polyoestrus, i.e., in the absence of pregnancy they exhibit repeated estrous cycles during the late spring to early autumn (Hughes *et al.*, 1975) (Table 1). In the winter, the archetypal mare enters a period of deep anestrus characterized by profound ovarian inactivity, i.e., little or no follicle development and no functional corpus luteum. As the days lengthen in the spring, the mare passes into a ‘transitional phase’ characterized by the growth of follicles that fail to mature and ovulate (Nagy *et al.*, 2000). The principle stimulus to the onset of seasonal cyclicity is day-length, mediated primarily by melatonin secreted by the pineal gland exclusively during periods of darkness. Longer days/shorter nights restrict the periods of melatonin secretion, thereby removing a ‘physiological brake’ on hypothalamic secretion of the major stimulator of the reproductive endocrine axis, gonadotrophin releasing hormone (GnRH). Neuroendocrine pathways involving kisspeptin and dopamine-prolactin are also known to be involved in the control of seasonal reproductive cyclicity (Williams *et al.*, 2012) and, while it is not clear exactly how they are stimulated or controlled, they almost certainly feed in at the level of the hypothalamus, facilitating the increased frequency and amplitude of pulsatile GnRH release. GnRH secreted from the hypothalamus enters specific hypothalamic-pituitary portal vessels that transport it to the anterior pituitary, where it stimulates the gonadotrope cells to secrete follicle stimulating hormone (FSH) and luteinizing hormone (LH). While the follicles that develop during the spring transition fail to ovulate, they do produce estrogens that in turn stimulate the mare to display sexual receptivity, either intermittently or for a prolonged period, a phenomenon known as ‘spring estrus’. The spring transition ends, and cyclical period begins, when the pituitary is able to generate an ‘LH surge’ capable of inducing ovulation (Williams *et al.*, 2012).

Table 1 Reproductive cycle parameters in the mare

	Mean	Range	Comments
Natural onset of seasonal cyclicity	Early April	March to May	Depends on breed, body condition, environmental temperature, exposure to other horses
Estrous cycle duration	21 days	17–24 days	Shorter in mid-summer Breed differences
Diestrus (luteal phase)	15 days	13–15 days	
Estrus (Follicular phase)	6 days	3–9 days	Shorter in mid-summer
Size of pre-ovulatory follicle	40 mm	30–60 mm	Consistent within individual mares. Breed differences
Follicle size at deviation	22 mm		Onset of LH-dependence Follicle dominance

While increasing day-length is the primary instigator of the spring transition, there are other contributors, including environmental temperature, body condition or nutritional plane, and pheromonal cues transmitted by close contact with stallions or other, cycling, mares (Nagy *et al.*, 2000). With respect to nutrition, mares in good to excessive body condition may cycle year-round, or show a shorter depth and duration of winter anestrus. A rising plane of nutrition can also hasten the spring transition. From a practical perspective, most horse registries assign an arbitrary birth date of January 1st. Since horses of some breeds (e.g., Thoroughbred racehorses) compete as juveniles (2–3 years old) or are sold via public auctions as foals or yearlings, there is considerable commercial pressure to ensure that foals are born early in the year so that they are more mature than their peers at the time of sale or racing. To aid this process, it is common to stimulate early seasonal cyclicity by exposing mares to ‘artificial long days’ (up to 16 h light) by providing additional lighting at dusk from late December (Nagy *et al.*, 2000).

The Estrous Cycle

The estrous cycle in the mare has a mean duration of 21 days, divided over a luteal or diestrous phase (progesterone dominance) of relatively constant duration (14–15 days) interspersed with follicular or estrous phases (estrogen dominance: period of sexual receptivity) of more variable duration (mean of 5–7 days: Hughes *et al.* (1975), Aurich (2011); Table 1). While recruitment of pre-antral follicles to the growing pool is probably gonadotropin independent, a ‘wave’ of small antral follicles develops FSH responsiveness and is stimulated to develop further by one of the FSH peaks that occur at approximately 10 day intervals. When the largest follicle(s) in a wave reaches 22 mm in diameter, one (occasionally two or more) is ‘selected’ for dominance and switches from FSH to LH dependence, allowing LH to promote further growth and maturation (Donadeu and Pedersen, 2008). The other (subordinate) follicles do not make this transition and instead shrink and become atretic. Indeed, the dominant follicle produces hormones (e.g., estrogens and inhibin) that suppress FSH release, thereby removing trophic support to the subordinate follicles. When growth of the dominant follicle to pre-ovulatory size (35–60 mm; varying between breeds and individuals) coincides with the end of the luteal (progesterone dominated) phase, a positive feedback between follicular estrogens and pituitary LH develops that generates the ‘surge’ in LH release that stimulates final follicle maturation and ovulation. By contrast, if a large follicle develops midway through the luteal phase it will not usually ovulate because circulating progesterone inhibits LH release and prevents the development of an ovulatory surge. In fact, the LH surge in mares is more gradual and prolonged than in other domestic species, only reaching a peak 1–2 days after ovulation, in part because of the long circulating half-life of LH in the mare (Stabenfeldt *et al.*, 1975). However, a relatively modest rise in LH is sufficient to trigger ovulation approximately 40 h later, about 10 h after an acute increase in intra-follicular prostaglandins (E2 and F2 α : Sirois and Doré (1997)) thought to be instrumental to weakening and rupture of the follicle wall. That relatively little LH is required to induce ovulation presumably explains why diestrous (mid-cycle) ovulation is more common in the mare than other species. The anatomy of follicle rupture highlights another peculiarity of the mare, namely that the ovarian cortex in which the follicles are situated is surrounded by both a vascular medulla and a thick tunica albuginea, rather than being located peripherally as in other species (Stabenfeldt *et al.*, 1975). The cortex reaches the surface of the ovary only at the ‘ovulation fossa’, which thanks to the absence of the tough overlying tunica, is the only site at which a follicle can rupture and release its oocyte into the adjacent oviductal infundibulum. When combined with the large size of equine pre-ovulatory follicles, the need to ovulate via the restricted fossa imposes a spatial impediment to ovulation of more than one follicle simultaneously, and undoubtedly contributes to the difficulty in stimulating multiple ovulation in mares.

Following ovulation, the ruptured follicle fills with blood to form a ‘corpus haemorrhagicum’, within which granulosa cells from the follicle wall migrate, and are transformed by LH (‘luteinized’) into luteal cells that organize the blood clot to form a highly vascular, progesterone-secreting corpus luteum (CL), the dominant endocrine organ of diestrus and early pregnancy. In the mare, the post-ovulatory rise in circulating progesterone is rapid, exceeding the 1 ng/mL that suppresses estrous behavior within 24–36 h, and continuing to a peak at around 8 days after ovulation. Luteal progesterone secretion then plateaus until day 13–14 when, in the absence of pregnancy, luteolysis (i.e., functional destruction of the CL) is triggered abruptly. Although the precise endocrine conditions that establish and initiate luteolysis are not known, a period of 8–10 days of progesterone priming enables oxytocin receptors to develop in the endometrium. By day 12–13 of diestrus, the endometrial oxytocin receptor population is sufficient to allow oxytocin, produced either in the hypothalamus and secreted from the posterior pituitary or produced locally within the endometrium, to bind to the endometrial receptors and trigger the release of the uterine luteolysin, PGF2 α . In turn, PGF2 α stimulates further release of oxytocin, thereby completing a positive feedback loop that results in the generation of the large pulses of PGF2 α (de Ruijter-Villani *et al.*, 2015) required to bring about functional demise of the CL and the associated precipitous fall (within 24 h) in circulating progesterone concentrations. For various reasons, e.g., reduced PGF2 α production capacity of degenerate endometrium, spontaneous failure of luteolysis leading to prolonged CL survival (typically 60–90 days) in the absence of pregnancy, is relatively common in the mare (Stabenfeldt *et al.*, 1975).

Mating, Fertilization and Tubal Development of the Embryo

Estrous behavior in the mare (sexual receptivity) is determined primarily by the absence of progesterone (<1 ng/mL), with rising estrogen concentrations serving to enhance the intensity of expression. Although there are significant individual variations, mares

are typically demonstrative in their expression of sexual receptivity. During progesterone dominance (e.g., diestrus or early pregnancy), mares react aggressively to the approach of a stallion (i.e., squeal, bite or kick) making it clear that his attention is unwelcome (Aurich, 2011). In the absence of progesterone, a mare's behavior can vary, or progress, from passive acceptance of a stallion's presence to actively seeking him out and demonstrating her readiness to mate by straddling her hind legs and elevating her tail; more intense displays to a stallion include rhythmic clitoral eversion ('winking') and/or micturition of a thick cloudy pheromone-laden urine that stimulates stallion interest. Even though estrogen concentrations decline from 1 to 2 days prior to ovulation, the mare will continue to display estrus until progesterone concentrations rise above 1 ng/mL, 1–2 days after ovulation. Assuming that a mare is mated naturally or inseminated artificially with freshly collected semen, it is assumed that the spermatozoa enter an oviductal 'sperm reservoir' by binding to oviduct epithelial cells in the distal isthmus of the oviduct (adjacent to the uterotubal junction); these spermatozoa retain their fertilizing capacity for at least 48 h.

LH stimulation of final follicle maturation 'reawakens' the oocyte to resume meiosis such that, at the time of ovulation, the oocyte has reached metaphase of the second meiotic division (MII) and is ready to be fertilized. The ovulated oocyte contained within an investment of supporting cumulus cells is 'caught' by the oviductal fimbriae, even though only a small proportion of the 40–50 mL of fluid evacuated from the follicle enters the oviduct; the cumulus-oocyte complex is then channeled via the infundibulum into the ampulla to await fertilization. At this point, a small number of the spermatozoa stored in the isthmus are activated ('capacitated'), by an as yet undefined signal, to detach from the oviduct epithelium and ascend through the isthmus to the ampulla, where they pass through the 'expanded' cumulus investment and bind to the outer coat of the oocyte (the zona pellucida). A single sperm will penetrate the zona pellucida, enter the perivitelline space and fuse with the oocyte to deliver its haploid packet of chromosomes and trigger fertilization.

After fertilization, the equine embryo remains in the oviduct for an unusually long time, approximately 6 days (Table 2), before descending into the uterus as a compacted morula comprising hundreds of morphologically indistinguishable cells. In fact, developing embryos are selectively transported into the uterus, whereas unfertilized oocytes are retained within the ampulla where they slowly degenerate. The key to this 'selective oviductal transport' is embryonic production of prostaglandins, principally PGE₂, from approximately day 5 after fertilization; PGE₂ relaxes the circular muscle of the oviductal isthmus causing it to dilate and allow the embryo to pass rapidly through and into the uterine lumen (Weber *et al.*, 1995).

Early Uterine Development

Soon after its arrival in the uterus on day 6, the horse embryo displays the first signs of cell lineage segregation, namely the coalescence of inter-cellular vacuoles to form a central cavity (blastocoel) lined by differentiated trophoblast cells, and within which the pluripotent cells aggregate to form the inner cell mass. At this point, the embryo is still surrounded by its original coat, the zona pellucida. Coincident with uterine entry, however, a second embryo coat known as the blastocyst 'capsule' forms within the perivitelline space between the trophoblast and zona pellucida (Table 2). When the embryo 'hatches' from the zona on day 7, as a result of rapid blastocyst expansion aided, presumably, by trophoblastic and/or endometrial proteases, the capsule persists. The capsule is initially composed of trophoblast-derived, mucin-like glycoproteins; however, these

Table 2 Timing of important events during equine pregnancy

Event	Time	Comments
Embryo descent into uterus	Day 6	Unfertilized oocytes remain in oviduct
Blastocyst formation	Day 7	Segregation of trophoblast and inner cell mass
Blastocyst capsule formation	Day 6–7	Embryonic glycoproteins require uterine contribution to coalesce
Zona pellucida loss (hatching)	Day 7	Soon after uterine entry & capsule formation
Yolk sac completed	Day 8	Primitive endoderm lines trophoblast
Conceptus migration phase	Days 6–16	Prostaglandins involved in propulsion Essential for maternal pregnancy recognition
Conceptus fixation	Day 16	Base of a uterine horn Coincident with capsule desialylation
Blastocyst capsule disintegration	Days 21–23	Disappearance completed around day 28
Apposition and adhesion phases of implantation	Days 22–40	Associated with formation and initial expansion of chorioallantois
Endometrial cup formation	Day 35–40	Chorionic girdle cells detach from conceptus and invade endometrium
eCG secretion/secondary CLs	Days 35–140	Varies between pregnancies (and equid genus)
Onset of placentation	Day 40	Stable microvillous attachment of chorion to endometrium
Microcotyledon development	Days 40–90	Secondary and tertiary branches increase surface area
Placental progesterone production	Day 60-term	Primarily 5 α DHP (very little native progesterone) Able to maintain pregnancy soon after day 70
Fetal-placental estrogen production	Day 60-term	Correlated with fetal gonad enlargement Peaks at about day 240
Foaling/parturition	Day 335–345	Enormous range (320–370 days). Depends on breed, parity, fetal sex, time of year

embryonic substrates require an unknown uterine contribution to coalesce into a confluent layer (Stout, 2016). Once formed, the capsule increases progressively in size and mass up to day 18, with endometrial proteins contributing significantly to this growth. While the functions of the capsule are not completely understood, it is essential for intra-uterine survival of the early embryo, and instrumental to maintaining the spherical shape of the rapidly expanding vesicle. The capsule also provides essential mechanical protection to the delicate yolk-sac vesicle during the period of intrauterine migration, and is present at the embryo-maternal interface during a period when the mobile conceptus must signal its presence to ensure 'maternal recognition of pregnancy', and harvest sufficient nutrients from the proteinaceous uterine secretions (histotroph) to support continued growth and development. It has been proposed that the capsule aids these processes by sequestering transport molecules that store or transmit biochemical signals or nutrients between the conceptus and endometrium (Stout, 2016). The capsule has also been proposed to protect against microbial or maternal immunological attack, and there is compelling evidence that it facilitates conceptus migration. In the latter respect, the abundant negatively charged sialic acid residues of the mucin-like capsular glycoproteins are thought to inhibit adhesion to the endometrium. Indeed, the end of the mobile period at day 16 is temporally associated with extensive desialylation of the capsular glycoproteins (Quinn *et al.*, 2007). With its role presumably completed, the capsule decreases in mass from around day 18, and by day 23 has lost its structural integrity and begun to disintegrate (Table 2); disappearance is completed by around day 28 (Allen and Wilsher, 2009).

Conceptus Migration and the Maternal Recognition of Pregnancy

During days 6–16, the equine conceptus vesicle expands rapidly (0.2 mm on day 6; 2 mm on day 10; 20 mm on day 14) but remains spherical and completely unattached to the uterine wall. Instead, the conceptus migrates continuously throughout the uterine lumen, propelled by myometrial contractions stimulated by prostaglandins either secreted by the conceptus or produced locally in the uterine wall in response to other conceptus products (Stout, 2016). Migration has been proposed to serve two major functions; (1) efficient harvesting of nutrients or growth factors from the uterine secretions, and (2) dispersal of the conceptus 'maternal recognition of pregnancy factor' (Table 2). Maternal recognition of pregnancy (MRP) involves the transmission of a biochemical signal(s) from the conceptus to its dam, to ensure that she makes the physiological changes required to support the continued survival and development of that conceptus. Since the most obvious outcome of MRP signaling is prolonged survival of the primary CL, MRP is generally taken to refer specifically to the processes involved in preventing luteal demise, and thereby ensuring ongoing provision of the progesterone required to maintain a qualitatively and quantitatively adequate supply of histotroph. Although the identity of the equine conceptus antiluteolytic factor(s) is not known, studies in which conceptuses failed to prevent luteolysis when restricted to a single uterine horn indicate that conceptus migration is critical to MRP signal transmission (McDowell *et al.*, 1988), just as blastocyst elongation ensures direct exposure of as much endometrium as possible to the MRP signals in pigs and ruminants. In fact, the spherical horse conceptus must deliver its anti-luteolytic signal to, and prevent PGF2 α release from, the entire endometrium rather than just the horn ipsilateral to the CL because the mare lacks the intimate intertwining of uterine vein and utero-ovarian artery that allows direct transfer of PGF2 α from the uterus to the ipsilateral ovary in ruminants; instead endometrial PGF2 α reaches the ovaries via the systemic circulation in the mare. Mechanistically, it appears that the equine conceptus disables luteolysis by a combination of suppressing the expression or binding affinity of endometrial oxytocin and PGF2 α receptors involved in the reciprocal stimulation loop that generates luteolytic PGF2 α pulses, and suppressing endometrial expression of prostaglandin endo-peroxide synthase 2 (PTGS2), an enzyme critical to PGF2 α synthesis (de Ruijter-Villani *et al.*, 2015).

Conceptus Fixation, Adhesion and Preparation for Implantation

After prolonging CL lifespan, the conceptus ceases to migrate and instead becomes lodged ('fixed'), at the base of a uterine horn as a result of its increasing diameter combined with a marked increase in uterine tone. The trophoctoderm and endometrium are still not in direct contact, however, because of the interposed capsule. Nevertheless, after vesicle fixation the capsular glycoproteins begin to undergo structural modifications, including desialylation and degradation of integral proteins (Quinn *et al.*, 2007), followed by attenuation, and culminating in a loss of structural integrity between days 21 and 23. Capsule disintegration allows the apposition and adhesion phases of implantation to begin and, not surprisingly, is associated with extensive upregulation, in both endometrium and trophoctoderm, of genes implicated in the implantation process in other species (Stout, 2016). In the diaspora following fixation and preceding stable placental attachment, it is likely that conceptus secretion of large quantities of estrogens and other vasoactive factors supports increasing nutrient demands by inducing an intense local endometrial hyperaemia and increased uterine blood flow; removal of the capsular barrier should also facilitate nutrient transfer. In addition, soon after fixation the embryo develops a primitive heart, blood cells and intra and extra-embryonic blood vessels yielding a functional circulation that will help deliver yolk-sac imbibed nutrients and oxygen to the developing embryo. The transition to a true placenta begins around day 20 with the development of the allantois as an outgrowth from the embryonic hindgut. By day 22, the allantois has enlarged to abut and fuse with the overlying chorion to form the chorioallantois which, during the coming days and weeks, will develop and vascularize in preparation for definitive placentation (Allen and Wilsher, 2009).

Implantation: Endometrial Cup Formation and Placental Interdigitation

Establishment of a stable placental attachment is preceded by an enigmatic invasive ‘implantation event’ involving a discrete band of specialized trophoctoderm cells that develop at the junction of the expanding allantois and regressing yolk-sac. These invasive trophoctoderm cells proliferate rapidly and pile up to form a distinct white band known as the ‘chorionic girdle’. At approximately day 35, the chorionic girdle cells detach from the conceptus, adhere to the endometrium and begin to invade via the endometrial glands (Table 2); the girdle cells pass through the epithelial basement membrane and into the endometrial stroma where they become binucleate, and cease to divide or invade further (Allen and Wilsheer, 2009). Here, the girdle cells organize into temporary endocrine structures known as the endometrial cups, which secrete large quantities of equine chorionic gonadotrophin (eCG), a hormone with considerable FSH-like activity in non-equid species. In the horse, eCG is almost exclusively LH-like in its effects, presumably to prevent overstimulating and wasting the ovarian follicle reserve during pregnancy, and instead stimulates steroid hormone (primarily progesterone) secretion by the primary CL and induces ovulation or luteinization of any medium to large follicles that develop under the influence of the ongoing waves of pituitary FSH production, resulting in the so-called secondary (ovulated) or accessory (non-ruptured, luteinized) corpora lutea. These additional CLs boost circulating progesterone concentrations, thereby acting as a ‘fail safe’ against loss of progestagenic support during the transition from ovarian to placental production. The endometrial cups are, however, recognized as foreign and trigger an intense cell-mediated and humoral maternal immune response characterized by the appearance of large numbers of lymphocytes and other immune cells around the endometrial cups, and of anti-paternal antibodies in the maternal circulation. This immune reaction eventually leads to ‘rejection’ of the endometrial cups, which are sloughed off the endometrial surface somewhere around day 120–140 of gestation, accompanied by a fall in circulating eCG concentrations.

By day 35, the embryo proper has developed limb buds and precursors of all major organs, to become a fetus. Only 5 days later does the principle implantation event start in earnest with the development of a microvillous attachment between the outermost chorion and underlying endometrial luminal epithelium. This establishment of a stable placental attachment is accompanied by interdigitation of the blunt primary chorioallantoic villi with corresponding up-growths from the endometrium (sulci). As gestation progresses, the surface area of the non-invasive, epitheliochorial interface increases dramatically in two ways; (1) the chorioallantois elongates rapidly such that it extends throughout the gravid horn and uterine body by day 65, and has also lined the whole of the non-gravid horn by day 85; (2) secondary and tertiary branching of the primary villi, matched by the accommodating endometrial sulci, leads to the increasingly complex labyrinthine interface characteristic of the mature microcotyledons (Table 2). Together these developments hugely increase the total area over which nutrients and gases can be exchanged, thereby compensating for the relatively long diffusion pathway inherent to an epitheliochorial placenta. By mid-gestation, microcotyledon formation is essentially complete although, as gestation proceeds, the microcotyledons enlarge and remodel to meet the increasing nutritional demands of the growing fetus (Allen and Wilsheer, 2009). The need to interdigitate with the vast majority of the endometrial surface to provide sufficient placental exchange to support the late gestation fetus, explains why it is extremely rare for a mare to successfully carry twins to term.

Endocrine Support of Pregnancy

Maintenance of early equine pregnancy depends on ovarian progesterone, initially from the primary CL and, following endometrial cup formation, supplemented by secondary CLs. As the fetus and placenta grow, so do their endocrine capacities and, from around day 60, measurable quantities of placental-derived 5α -pregnan-3,20-dione (5α -DHP) and other progestagens appear in the maternal circulation (Ousey, 2012)(Table 2). A parallel increase in uterine blood flow means that increasing quantities of steroid precursors are delivered to the fetal circulation, where they can be metabolized into progestagens before being secreted back into the maternal circulation. Studies involving the ovariectomy of pregnant mares, suggest that placental progestagen production is sufficient to maintain pregnancy from soon after day 70.

Horse conceptuses also secrete large quantities of estrogens from as early as day 8, with proposed functions during early pregnancy including promotion of uterine blood flow and optimizing histotroph quality and production. However, early conceptus estrogens are not measurable in the mare’s circulation and, while maternal estrogen concentrations do rise after day 35, the initial source is the eCG-stimulated primary CL. From about day 80, maternal circulating estrogen concentrations rise again; this time they are derived from the fetal-placental unit and including large quantities of the equine pregnancy specific unsaturated estrogens, equilin, equilenin and their hydroxy-derivatives (Ousey, 2012). This mid-gestation rise in fetal-placental estrogens is based on an enormous enlargement of the fetal gonads which produce the primary estrogen precursor, DHEA, that is aromatized by the placenta to yield the estrogens that enter maternal blood. Fetal-placental estrogens appear to stimulate uterine blood flow, and oppose the quietening effects of progesterone on the myometrial smooth muscles as parturition approaches.

Parturition and Post-Partum Recovery

While the mean length of gestation in the mare is 335–345 days, the exact duration varies tremendously between individuals and is affected by time of year (gestation is shorter for foals born late in the year), maternal parity, breed and sex of the foal (Table 2).

Table 3 Major events at foaling and during post-partum recovery in the mare

Event	Timing	Comments
Endocrine changes associated with preparation for parturition	2–5 days before foaling	Fetal ACTH and cortisol release Falling maternal progestagens, Increased estrogen: progestagen ratio
Foaling	20–45 min	Rapid and forceful
Expulsion of fetal membranes	15–90 min post-foaling	Significant delay endangers mare health
Post-partum estrus	8–12 days after foaling	In 80% of mares
Uterine involution	14–21 days	Recovery of endometrial architecture Contraction of myometrial musculature
Arrival of foal heat embryo in uterus	From day 14 after foaling	Embryo remains 6 days in oviduct Survival compromised by delayed involution
Desired re-establishment of pregnancy	<30 days after foaling	To maintain yearly foal production

That ‘normal’ gestation can range from at least 320–370 days makes it difficult to predict when a mare will foal. This is not helped by the fact that, while the endocrine changes indicating preparation for parturition in other species are also seen in the mare, they are much more rapid, acute and are only detectable in the last few days before equine delivery (Fowden *et al.*, 2008) (Table 3). Nevertheless, the major drive to parturition appears to be an increase in fetal adrenal cortical activity (fetal stress), with the resulting fetal cortisol triggering a rise in the maternal estrogen: progestagen ratio. Increasing estrogen dominance activates various pathways associated with myometrial contractility, including increased uterine oxytocin receptor expression and PGF2 α production, and allows the onset of the uterine contractions characteristic of the first stage of labour (Ousey, 2012). Increasingly coordinated myometrial contractions cause the chorioallantois to bulge into a cervix relaxed by PGE2 of utero-placental origin and the resulting dilation of the cervix triggers release of hypothalamic-pituitary oxytocin, via the Ferguson reflex, to further stimulate uterine myometrial contractions both directly and by provoking further uterine PGF2 α release. Second stage labour (i.e., fetal delivery) begins once the chorioallantois has ruptured, is assisted by powerful abdominal contractions and is normally completed very rapidly, i.e., within about 30 min (Table 3). After delivery of the foal, release of the fetal components of the placenta (i.e., the chorioallantois) during third stage labour is also completed relatively rapidly, normally within 15–90 min of birth, presumably in part because each non-invasive microcotyledon can relatively easily disengage from its endometrial ‘glove’.

Post-partum uterine involution, i.e., discharge of pregnancy and parturition-related debris, remodeling of the endometrium and contraction of the uterus to something approaching its pre-gravid size, is also surprisingly rapid in the mare. Again the non-invasive nature of placentation may contribute to rapid recovery since the endometrium presumably has to undergo a comparatively modest repair and remodeling processes. The post-partum period also features the development of a mature ovarian follicle leading to a ‘post-partum’ estrus at around day 9 after foaling (Table 3). Rapid uterine involution means that mating at this ‘foal heat’ can lead to successful conception, although anything that delays involution will reduce the likelihood of establishing or maintaining pregnancy. Interestingly, post-partum follicle growth appears to be a specific phenomenon related to the endocrine conditions of late gestation; once the resulting CL has regressed, the mare may still return to seasonal anestrus if she foaled early in the year before the days started to lengthen.

Introduction

Research using animal models has played a vital role in virtually every major area of biomedicine, including our understanding of female reproduction. Among animals used in laboratory research, rodents have emerged as the model of choice. There are more than 2000 rodent species with diverse physiology and behavior. The mouse, rat, hamster, gerbil and guinea pig are the most commonly used rodents for laboratory research. Therefore, the genomes of mouse, rat, hamster, guinea pig and human have been sequenced. These genomes are composed of varying numbers of genes packaged in chromosomes. Based on size, the genome of the rat and guinea pig appears the closest to humans (Table 1).

Reproduction (sexual or asexual) is crucial for the purpose of genetic propagation to the next generation. Sexual reproduction includes inbreeding and outbreeding. The benefit of outbreeding males and females of the same species is the increased genetic variability due to exchange of genes. Conversely, inbreeding reduces the genetic diversity by increasing homozygosity leading to high risk of inheriting genetic diseases. Inbred homozygous animal models are preferred in biomedical studies in order to limit variations in experimental parameters. Unfortunately, the usage of a single inbred strain of species likely does not capture the genetic variations observed in outbred species like humans.

Reproductive Maturity and Cyclicity

Puberty

The chromosomal sex of the zygote (fertilized egg) determines the sexual phenotype of the offspring. The time of sexual differentiation varies among species. In long gestational species (human and guinea pig) sex differentiation occurs prenatally, but in short gestational species (mice and rats) it continues into the neonatal period. The reproductive ability of females begins at puberty, which is marked by the onset of the reproductive cycle: the estrous cycle in rodents and menstrual cycle (menarche) in humans. Rats begin cycling immediately after vaginal opening, whereas mice and hamster attain sexual maturity several days or weeks after their vaginal opening. The onset of the human menstrual cycle occurs between the ages of 8–12 (Table 1).

Anatomy of the Female Reproductive Tract

The female reproductive system consists of a pair of ovaries, each attached to fallopian tubes connected to either a single uterine body (human) or two separate uterine horns (bicornuate; rodents). The uterus is connected to a cervix to separate it from the vaginal canal. In rodents, the ovaries are encapsulated with a bursa (a thin membranous structure) to guard it from the peritoneal environment. The bursa is not continuous in humans, making a peritoneal ectopic pregnancy possible. In the majority of rodents, the bicornuate uterus leads into one cervix. However, in hamsters and chinchillas, the bicornuate uterus leads into two cervical canals.

Stages of the Reproductive Estrous Cycle

The estrous cycle length for the majority of commonly used laboratory rodents is shorter (4–5 days) than the less commonly used rodents which exhibit a lengthy cycle (greater than two weeks; Table 1). One factor underlying the extended period of estrous cycle in the guinea pig is formation of a functional corpus luteum (CL) in the absence of mating. This is very similar to humans where luteal phase continues for ~14 days after ovulation.

The estrous cycle of rodents is divided into four stages based on vaginal smear cytology and proportion of vaginal epithelial cells, cornified epithelial cells and leukocytes. In a standard 4-day cycle, the order of stages includes: 1) *proestrus*, the preovulatory day in which there is predominance of nucleated epithelial cells; 2) *estrus*, the day of ovulation and receptive phase for breeding whereby there are irregular-shaped, needle-like and enucleated cornified (or keratinized) squamous epithelial cells; 3) *metestrus*, the day of non-receptivity in which there is a mixture of cornified epithelial and leukocytes; and 4) *diestrus*, another day of non-receptivity whereby there is a predominance of leukocytes (Deb et al., 2006). When determining the stage of estrus, it is important to note that: 1) the regular estrous cycle in mice is not as distinct as rats and hamsters; 2) it is possible that the day of estrus or diestrus lasts for 2 consecutive days, thereby creating a five day cycle; and 3) sometimes a vaginal smear may reflect a transitory period between estrous cycle days.

The major differences between the reproductive cycle of rodents and humans are the longer cycle length (~28–30 days; Table 1) and uterine cyclic changes, including menstruation. In humans, the beginning of the menstrual cycle is marked by the shedding of uterine endometrium (menstruation), which lasts ~3–7 days. Similar to rodents, the menstrual cycle is divided into phases based on ovarian or uterine changes, which are described in detail below. During each reproductive cycle of most rodents and humans,

^aSpecies dependent; males and female have different chromosome numbers; female have chromosome from both sexes.^bCopulatory plug or presence of sperm in vaginal smear = day 1 of pregnancy.

ovulation occurs spontaneously regardless of mating with male. However, in some rodents such as voles, ovulation is induced by vaginal stimulation from copulation with a male (Jemiolo, 1983) (Table 1).

Hormonal Changes During the Estrous Cycle

In mammals, the reproductive cycle is regulated by cyclic variations in the levels of: 1) peptide hormones from the hypothalamus and pituitary gland and 2) steroid hormones from the ovary. The gonadotropin releasing hormone (GnRH) of the hypothalamus triggers the secretion of follicle stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary. FSH is responsible for stimulating ovarian follicular growth and estrogen (E) production by the developing follicle. LH triggers oocyte release from the mature follicle (ovulation) and development of corpus luteum (CL) which secretes more progesterone (P_4) than E (Christensen *et al.*, 2012).

The differences observed in the levels of pituitary and ovarian hormones among rodent species during their estrous cycles are detailed below:

- 1) Mouse: The proestrous phase corresponds to an increase in E levels followed by increased release of FSH and LH into the circulation. During estrus, E levels decline. P_4 levels start to rise during metestrus, peak during diestrus and then decline until estrus (McLean *et al.*, 2012).
- 2) Rats: Unlike the mouse, serum E levels remain elevated during the early part of estrus, before returning to basal levels on the afternoon of estrus. Moreover, serum P_4 levels of this species significantly increase during the transition from proestrus to estrus, following peak levels of FSH and LH, which is different compared to mice.
- 3) Hamster: Unlike the variable 4–5 day cycle length of rats and mice, hamsters exhibit a regular 4 day cycle. Serum FSH and LH levels peak on the afternoon of proestrus prior to ovulation. In hamsters, FSH shows another peak on the morning of the estrus (unlike mouse and rats). E and P_4 levels show an inverse relationship during the cycle. E secretion markedly increases a full day prior to LH release, but P_4 secretion begins only in response to the LH surge.
- 4) Gerbil: Serum FSH and LH levels peak at proestrus and estrus, respectively. Serum E levels peak at proestrus and displayed no significant difference throughout the estrus, metestrus or diestrus stages. Serum P_4 levels remain constant through proestrus, metestrus and diestrus stages, peaking at estrus.
- 5) Guinea pig: Little information is available regarding the changes in E and P_4 levels during the estrous cycle of guinea pigs, largely due to the relatively lengthy 16 day cycle. E levels are elevated during proestrus and beginning of preovulatory estrus, thereby preceding the preovulatory LH peak. There is no preovulatory FSH peak. The peak levels of plasma P_4 are observed on luteal phase of the cycle (day 12) and fall thereafter, reaching extremely low levels on day 1 of the cycle.

As shown in Fig. 1, the major difference in hormonal changes between the estrous and menstrual cycle is the slight secondary increase in E levels during the middle of the post-ovulatory (luteal) phase.

Ovarian Changes During the Cycle

The ovary contains its maximum number (millions) of oocytes at birth, which then deplete in number from puberty to menopause. In each reproductive cycle of humans and rodents, several ovarian follicles containing an oocyte begin to grow or mature. During the follicular maturation period, at least one follicle in humans, and more than one follicle in rodents, becomes dominant and grows faster than others; marking the major difference in ovarian changes between humans and rodents. The stages of follicular development include: primordial → primary → secondary → tertiary (or Graafian) follicles.

Based on follicular changes, the ovarian cycle of rodents and humans is divided into three phases (Schank and McClintock, 1992):

- 1) Preovulatory phase (follicular phase) is defined as the follicular growth and maturation for ovulation. The follicular phase occurs during the proestrus stage of rodents, and uterine proliferative phase of humans.
- 2) Ovulatory phase (ovulation) is the event of oocyte release from the follicle and is defined as estrus/heat/lordosis in which the female exhibits maximum sexual motivation and receptivity.
- 3) Postovulatory phase (luteal phase) occurs when Graafian follicles, in the absence of their oocyte, develop into CL. The CL secretes P_4 during the luteal phase. The luteal phase is analogous to the metestrus and diestrus of rodents, and uterine secretory phase of the human cycle.

During the proestrus stage, follicles grow and mature into Graafian follicles. The estrus stage of the cycle is recognized by the presence of newly formed CL and the absence of Graafian follicles. At metestrus, the luteal cells of the CL begin producing P_4 . The functional demise of the CL (referred to as luteolysis) begins at the end of metestrus and continues to diestrus. Presence of a maximally-sized CL is the best marker of a diestrus ovary. Luteolysis is visible in the diestrus stage and results in decreased P_4 synthesis, which releases inhibition of LH secretion, allowing proestrus to begin. Although the aforementioned ovarian changes occur during the rodent estrous cycle, the specific stage is difficult to discern by ovarian morphology alone, since all stages contain follicles in each phase of development as well as multiple generations of CL. A regressed CL remains in the ovary for 10–15 days in most rodents, except hamsters which show no presence of CL in their next cycle.

Fig. 1 A schematic drawing of hormonal profiles during female reproductive cycles of rodents and humans.

Uterine Changes During the Cycle

At proestrus, the rodent uterus is somewhat distended due to fluid accumulation. Uterine luminal epithelial (LE) cells become columnar shaped and proliferate. Stromal edema is also observed at proestrus. During the estrus stage, the uterus is fully distended and has maximum secretory activity due to a pronounced increase in the endometrial extracellular fluid. During estrus, proliferation occurs in the stroma but not epithelium. At metestrus, proliferation occurs in luminal and glandular epithelial cells, simultaneous to apoptosis of stromal cells as well as the proliferating LE cells. Finally, during the diestrus stage, the rodent uterus is small and poorly vascularized, with a collapsed lumen.

There are key differences between the uterine changes occurring in the estrous and menstrual cycles. In the human, the cyclic uterus undergoes changes to achieve receptivity and stromal cell decidualization in order to support the possible presence of a blastocyst for implantation. The human uterine cyclic changes are divided into three phases (Mihm *et al.*, 2011):

- 1) Menstrual phase is the event of endometrial shedding occurring the first 4–7 days of the cycle.
- 2) Proliferative phase is defined by uterine endometrial regrowth, lasting ~10 days between the menstrual and secretory phases. After menstruation, ovarian follicular E production stimulates the proliferation of endometrial epithelial, glandular and endothelial cells, thereby increasing the uterine lining thickness.
- 3) Secretory phase is characterized by an increase in endometrial secretory activity corresponding to the ovarian luteal phase, lasting ~14 days after ovulation on day 14. On cycle days 16–20, endometrial glands become more tortuous and dilated, and accumulate glycogen. On cycle days 21 and 22, the endometrial stroma begins becoming edematous. On cycle days 23–25, stromal mitosis is apparent. Predecidual cells appear first around the spiral arterioles and later under the LE. On cycle day 27, there is a marked lymphocytic infiltration and endometrial stroma appears as a solid sheet of well-developed decidual-like cells.

Regulation of the Reproductive Cycle by the Hypothalamic-Pituitary-Ovarian Axis

Transition from the prepubertal period to puberty is marked by increase in GnRH production. Upon the onset of puberty, occurrence of repeated regular cycles is a function of phasic production and secretion of hormones from the hypothalamus, pituitary and ovary. As shown in Fig. 2, hypothalamic GnRH stimulates pituitary production of FSH and LH which then act on the ovary. Under the control of FSH during the late stage of the proestrus in rodents and follicular phase in humans, follicles grow and produce increased levels of E, causing a positive feedback loop for additional FSH and LH production by the anterior pituitary. Under the control of LH during early estrus in rodents and ovulatory phase in humans, ovulation occurs and mature follicles are transformed into CLs. The CLs begin producing more P_4 than E, resulting in an inhibition of the hypothalamic-pituitary-ovarian positive

Fig. 2 A schematic view of the hypothalamus, pituitary and ovarian reproductive axis. E, estrogen; FSH, follicle stimulating hormone; LH, luteinizing hormone; GnRH, gonadotropin releasing hormone.

feedback loop. If pregnancy does not occur following ovulation, the CL undergoes luteolysis, resulting in decreased P_4 production, which in turn allows the hypothalamus to produce GnRH to resume the cycle (Mihm *et al.*, 2011).

Current dogma is that the occurrence of repeated regular cycles is a function of phasic ovarian E and P_4 secretion. However, E and P_4 receptor gene ablation studies in mice and rats suggest that while both ovarian E and P_4 functions are required for estrous cyclicity in mice, E but not P_4 function is needed for estrous cyclicity of rats. Perhaps, the maintenance of regular menstrual cycles in humans is also not dependent on functional P_4 , since women that are P_4 – resistant exhibit regular cycles with normal luteal phase duration (Kubota *et al.*, 2016).

Pregnancy Establishment

Identification of Pregnancy

Pregnancy begins when successful mating occurs around the time or day of ovulation, to allow fertilization of the egg. After a successful copulation, components of the male rodent ejaculate coagulate to form a plug occluding the vagina. The semen of humans coagulates to form a loose gel rather than a fibrous plug seen in rodents. The copulatory plug is used as an indicator of successful coitus in most rodents. However, the copulatory plugs do not stay in the vagina for as long of time in rats, gerbils or hamsters, compared to mice. Thus, the best method to ascertain mating in any species is the microscopic identification of sperm in a vaginal saline lavage. The estrous stage of the hamster cycle is also determined by visually inspecting the vaginal discharge.

Fertilization of the oocyte occurs within the fallopian tube. The window of fertilization lasts for a limited time span: 6 days in humans, but only hours in rodents due to the short survival time of sperm and egg. Remarkably in humans, an oocyte can survive for a day and sperm can remain active for up to 5 days.

The earliest that pregnancy can be identified in rodents is during blastocyst attachment to the uterus. At this time, due to an increase in localized vascular permeability, a macromolecular dye can be used to visualize sites of blastocyst attachment at various time points in early rodent pregnancy, as outlined in Table 1. In humans, blood or urine tests for human chorionic gonadotropin (hCG) levels allows a convenient method to identify early pregnancy following copulation, since hCG is increasingly produced by the syncytiotrophoblast after implantation.

Uterine Preparation for Pregnancy Establishment

In the event of fertilization, two processes occur in synchrony: 1) the CL survives and produces P_4 to prepare the uterus for embryo attachment and implantation, and 2) the fertilized egg mitotically divides to reach the blastocyst stage and migrates from the oviduct to the uterus. In general, the uterine preparation period from the day of fertilization to the day of blastocyst attachment is known as the preimplantation period. The preimplantation uterine changes begin on day 2 of pregnancy and continue until

implantation. The preimplantation uterine period is divided into prereceptive and receptive phases. During the prereceptive phase (days 2–4 in mice), the uterine LE is non-adhesive to the blastocyst. The receptive phase allows blastocyst implantation to occur during a limited window of opportunity known as the 'window of implantation'. In pregnant and pseudopregnant mice, the window extends from late day 4 of pregnancy to early day 5. In women, the window of receptivity begins on cycle day 19–20 and lasts for 4–5 days. After the uterine window of implantation, the uterus gradually loses its receptivity and becomes refractory to support blastocyst implantation (Dey *et al.*, 2004).

Steroid Hormones Required for Blastocyst Implantation

The preovulatory E secretion from the growing ovarian follicles induces uterine LE proliferation on day 2 of pregnancy, which is then suppressed by the postovulatory increase in P_4 secretion from the CL. Postovulatory P_4 influences the initiation of uterine stromal cell proliferation, allowing the uterus to acquire a receptive phenotype permissive to implantation. The period of uterine receptivity begins in a P_4 -primed uterus following a small elevation of circulating E levels in mice, rats and gerbils. In these species, the necessity of a small estrogen increase was ascertained by studies showing that removal of preimplantation estrogen elevation experimentally leads to a condition called "delayed implantation" (discussed in detail below). While a small spike of ovarian E secretion prior to blastocyst implantation is crucial for the initiation of implantation in rodents (like mice, rats and gerbils), it is not important for implantation in other rodents (such as guinea pigs and hamsters) (Fig. 3). The role of ovarian E in initiation of implantation in humans remains debatable. Since ovarian E secretion may not be necessary for blastocyst implantation in humans, hamsters or guinea pigs, it is possible that the blastocysts of these species are capable of producing E of which there are a handful of reports (Reese *et al.*, 2008).

Delayed Blastocyst Implantation

Any delay in blastocyst implantation, whether natural or experimental, is referred to as 'delayed implantation'. The growth arrest of the blastocyst prior to implantation can be considered as a quiescent (latent) period. The length of this latent period is dependent on the uterine ability to attain receptivity, and could last 1–2 days or even months depending on the species. Thus, preimplantation blastocyst latency within a prereceptive uterus is a protective phenomenon from an unfavorable uterine environment, and is an embryonic trait conserved across mammalian species. Rodents experience a lactational delay of blastocyst implantation due to a combination of postpartum estrus, mating and lactation. Immediately following parturition, rodents experience a fertile postpartum estrus. However, since rodents are nursing their offspring, the implantation of latent blastocysts occurs after the end of suckling stimulus (Mead, 1993).

Delayed implantation can be experimentally induced in rodents. To do so, mice, rats and gerbils are ovariectomized or hypophysectomized prior to the preimplantation ovarian E secretion in order to prevent the uterus from becoming receptive. Experimentally-induced delayed implantation can be maintained for several weeks with daily P_4 supplementation. However, a single low dosage injection of estradiol-17 (E_2) causes both the uterus and blastocyst to achieve implantation competency resulting in initiation of the implantation process. The experimental delay in implantation cannot be initiated in rodents such as hamsters and guinea pigs, whose implantation is P_4 -dependent (Paria *et al.*, 1993; Reese *et al.*, 2008). Experimentally-induced delayed implantation cannot be tested in humans due to ethical reasons.

There is no clinical data in humans concerning ovulatory status immediately after parturition and lactational delays in implantation. Clinical findings have showed that women undergo postpartum amenorrhea (the absence of menstrual cycle). The length of

Fig. 3 A schematic drawing of ovarian steroid hormonal profiles during early pregnancy in rodents and humans.

Fig. 4 A schematic depiction of early blastocyst implantation events.

amenorrhea varies depending on: 1) whether the woman is breastfeeding or not, 2) frequency and length of breast feeding, 3) maternal age and parity. Most women will not begin ovulating in the first 4–6 weeks after giving birth (McNeilly, 2001).

Key Events of Implantation and Decidualization

Embryo implantation and stromal cell decidualization are prerequisites for the establishment of pregnancy in the majority of mammals. Implantation involves a physical, molecular and physiological contact between the blastocyst and the uterus. It occurs in three phases: apposition, attachment and invasion. In rodents, the uterine LE enfolds creating small crypt-like structures called implantation chambers. The blastocyst within an implantation chamber gradually orients (apposition) and places itself within proximity to the LE, initiating the process of attachment. The orientation of the blastocyst during implantation differs between humans and rodents. In contrast to humans in which the polar trophoblast (embryonic side) of the blastocyst initiates the process of attachment, this process is initiated by the mural trophoblast (abembryonic side) of the rodent blastocyst (Fig. 4). In most species, blastocyst attachment occurs at the antimesometrial side of the uterus (Carson *et al.*, 2000).

Attachment of the trophoblast ensues immediately after the loss of zona pellucida (a membrane surrounding the blastocyst) except in guinea pigs where the trophoblast penetrates the zona pellucida to attach with the uterine LE. In mice and rats, initial attachment is loose, allowing the blastocyst to be flushed out of the uterus. However, in hamsters, the attachment reaction is extremely tight, making flushing of the blastocyst almost impossible. In rodents, the mural trophoblast cells stop dividing after attachment to the uterus, but continue to endoduplicate to form trophoblast giant cells. The polar trophoblast cells continue to proliferate, migrate towards the mesometrial side of the uterus and form a fully developed ectoplacental cone. In contrast to rodents, the human embryonic trophoblast not only attaches, but continues to proliferate and invade the endometrium (Carson *et al.*, 2000).

Based on the interaction between the blastocyst and uterus, the process of implantation has been classified into the following types (Carson *et al.*, 2000).

- 1) Centric (fusion or non-invasive) implantation occurs when the blastocyst makes extensive surface contact and fuses with the uterine LE without any penetration. Examples include: rabbits, dogs, domestic animals and several marsupials.
- 2) Eccentric (displacement) implantation occurs when the uterine LE forms an invagination to surround the abembryonic trophoblast. The trophoblast makes contact with stromal cells by displacing or shedding the underneath uterine LE. Examples include: rats, mice, hamsters and voles.
- 3) Interstitial (intrusive) implantation takes place when the trophoblast or the entire blastocyst invades through the LE to embed within the endometrial stroma. Examples include: humans, guinea pigs, gerbils and chinchilla.

The blastocyst-uterine attachment reaction is followed by decidualization, only at embryo implantation sites. Decidualization is common among many mammalian species, including rodents and humans. Decidualization occurs due to the proliferation of stromal cells and their transformation into decidual cells, which are polyploid and epithelioid-like. In humans, predecidual cells are observed at focal sites within the endometrium (surrounding the spiral arteries) during the late secretory phase of the cycle, in the presence or absence of the blastocyst. However, in rodents decidualization relies on contact of the blastocyst with the uterus. Therefore, decidual formation begins at the antimesometrial side of the implantation sites. Following initiation of the blastocyst-uterine attachment reaction, an avascular primary decidual zone (PDZ) is formed immediately underneath and lateral to the implanting embryo. Cells of the PDZ are tightly packed and epithelioid in nature. Later, proliferating stromal cells around the PDZ differentiate into decidual cells forming a secondary decidual zone (SDZ). In parallel to the antimesometrial decidual formation, stromal cells of the mesometrial side of the implanting embryo also proliferate and differentiate to the non-polyploid decidual zone (Gao *et al.*, 2015).

Decidualization can be experimentally-induced in pregnant, pseudopregnant or ovariectomized rodents. To do so, the uterus must be hormonally-primed for decidualization by various artificial means, such as an intraluminal oil injection, silk thread placement or surface scratching using a needle. In ovariectomized rodents, P₄ but not E₂, is an absolute requirement for induction of decidualization. The differential hormonal requirement of the uterus for artificial decidualization has been confirmed by the use of progesterone receptor knockout mice in which decidualoma formation is not possible, while artificial decidualization can occur

in P₄-primed ovariectomized estrogen receptor knockout mice (Paria *et al.*, 1999). While a physical stimulus is required to induce artificial-decidualization in rodents, it is unclear why a similar physical stimulus is not required for decidualization in humans.

Concluding Remarks

Reproductive cycle abnormalities, fertility issues and early pregnancy disorders in women are common reproductive health concerns that arise because of ovarian and uterine functional deficiencies. Examining key events and hormonal regulation of ovarian and uterine functions during the menstrual cycle and early pregnancy in human subjects remains problematic due to: 1) ethical and regulatory concerns; 2) inadequate patient health information, and 3) genetic diversity among humans. Therefore, researchers have relied on the use of rodent models; however no rodent model truly recapitulates all aspects of the human reproductive cycle and early pregnancy. Here, we highlighted the similarities and differences that exist among the most commonly used laboratory rodent species, as well as between rodents and humans. Different rodent models may be better suited to study specific steps in the processes involved in human reproductive cycle and early pregnancy. Comparative genomic analysis of humans and laboratory rodents, as well as extension of genetic manipulation techniques from the mouse to other rodent species, will allow generation of meaningful data that can be applied to human reproduction.

Selected Comparative Aspects of Canine Female Reproductive Physiology

Mariusz P Kowalewski, University of Zurich, Zurich, Switzerland

Introduction

Why the Dog?

In recent years, considerable progress has been achieved in understanding reproductive physiology in the domestic dog, in particular regarding female reproduction.

This was driven by the following underlying facts:

1. The dog is one of the most suitable laboratory animal models. Out of over 711 traits/disorders currently (Oct. 2017) listed in the Online Mendelian Inheritance in Animals (OMIA) database for the dog, 413 present potential models for human diseases. Other domestic animals trail with a maximum of roughly 200 possible models, e.g. for cattle and cats, and less for others. Mostly for social reasons, the potential of the dog as a model animal is not fully utilized in research studies.
2. The dog is among the most important laboratory animals in pharmacological and toxicological studies.
3. Social aspects: the domestic dog is among the most important pets and veterinary patients. Thus, social and economic interest in better understanding of canine reproduction is justified. Many clinical issues are still not solved, such as luteal insufficiency and endometrial hyperplasia/pyometra complex, because basic regulatory processes are not yet fully understood in this species. Consequently, several therapeutic approaches are based solely upon clinical experience and empirical evidence, rather than on understanding of underlying molecular biological processes.
4. Due to several species-specific regulatory mechanisms, possibilities for translational research to be adapted from other species to dogs are limited. This underlines the importance of the dog as an interesting model for investigating comparative aspects of reproductive physiology in other mammals, broadening the horizons and even breaking some of the existing dogma.
5. In taxonomically-related endangered species, the domestic dog could be used as a valuable model for studying reproduction and developing assisted reproduction techniques.

Goals

Here, a general overview of reproductive cycles in pregnant and non-pregnant dogs is presented. Species-specific peculiarities and comparative aspects are emphasized. Focusing on endocrine regulatory processes, the most recent developments in understanding canine female reproductive physiology are presented. These include ovarian and luteal function, embryo-maternal oviductal and uterine communication and the feto-maternal utero-placental dialog, during the establishment, maintenance and termination of canine gestation.

Original research papers and reviews published from our and other laboratories were used to gather the information presented herein.

More comprehensive reviews and details regarding source publications can be found in (Concannon, 2009, 2011; Feldman and Nelson, 2004; Hoffmann *et al.*, 2004; Kowalewski, 2014, 2017; Kowalewski *et al.*, 2015; Wright, 2017). In this respect, noteworthy is the pioneering work on canine reproductive physiology, dating from the middle of the 19th century (1845), by the German researcher and at that time professor at the University in Giessen, Theodor Ludwig Wilhelm von Bischoff (Bischoff, 1845). Even though at that time the role of the corpus luteum was not known, and progesterone (P4) was not yet isolated (not until the beginning of the 20th century), von Bischoff, among others, with a great deal of detail, for the first time described the process of preovulatory luteinization in the dog.

What Makes the Dog Special? – Species-Specific Peculiarities of Canine Reproduction at a Glance

The sexual cycle in the domestic dog is exceptionally long compared with other domestic animal species, showing tremendous breed and individual variations with regard to the length of the particular phases of the cycle (Fig. 1). Corpora lutea (CL) are the only major source of circulating steroids in the female dog, both in pregnant and non-pregnant bitches. Because of this, the dog is the only domestic animal species not producing steroids in the placenta, and thus is fully reliant on luteal steroids for successful pregnancy. This also underlines the central role of CL in controlling canine reproduction. Compared with other domestic animal species, canine CL require a longer time to fully attain their maximal steroidogenic capacities (around days 15 to 30 after ovulation). At the time of implantation, the uterus is exposed to relatively high P4 concentrations, apparently much higher than those required for the maintenance of pregnancy. Hysterectomy does not affect ovarian cyclicity in the dog, neither could substantial production of luteolysin (PGF2 α) be confirmed in the CL of pregnant or non-pregnant bitches. The sexually active phases are always separated by an obligatory quiescence (resting) phase, referred to as anestrus. One of the biggest peculiarities is the lack of an antiluteolytic principle in the absence of pregnancy, resulting in a physiological pseudopregnancy. This, along with similar secretion patterns of circulating steroids in pregnant and non-pregnant bitches, precludes P4 as a reliable marker for pregnancy detection in

Fig. 1 The canine reproductive cycle.

dogs. Pseudopregnancy can last at least as long as, or even exceed, the time span of normal pregnancy. Consequently, the classical definition of embryo-maternal recognition of pregnancy, understood to be the existence of different strategies evolutionarily established for preventing luteolysis and allowing the CL to persist in order for pregnancy to succeed, also does not apply in the dog. Instead another, more general definition was proposed for the dog as more suitable (Kowalewski *et al.*, 2015). Accordingly, in the canine species the maternal recognition of pregnancy appears to involve morphological and functional interplay between the uterus, the embryo, and the CL as the only provider of P4.

Further, in the domestic dog, as in other *Canidae*, immature oocytes are ovulated at the primary oocyte stage. They require a further 2–3 days of oviductal maturation, only then acquiring the developmental stage of fertile secondary oocytes. This makes the dog an absolute exception among domestic animal species in which the resumption of meiosis and completion of the chromosome reduction division is stimulated by the preovulatory LH surge and takes place before ovulation. In other words, whereas in all other domestic animal species oocytes are ovulated as secondary oocytes, in the dog primary oocytes are ovulated. This also greatly complicates artificial reproduction techniques (ART) applications in dogs because information on the requirements for completion of oocyte meiosis in vitro is sorely lacking, unlike in several other domesticated animal species such as cattle.

Also contrasting with other domestic animal species, including the cat, is the absence of a pregnancy or prepartum/parturition-related increase of estrogens in the dog. The prepartum signaling cascade appears, therefore, also to follow species-specific regulatory mechanisms.

Finally, regarding luteotropic support, although hypophyseal hormones, (predominantly) PRL and LH, are required for luteal maintenance during the second half of the canine luteal phase, luteal regression occurs in spite of increasing availability of both circulating PRL and LH. Although gestational PRL levels are increased when compared with pseudopregnancy, they cannot be used for detection of pregnancy because elevated levels of this hormone can be also observed in clinical condition of overt pseudopregnancy (*Lactatio sine graviditate* or *Lactatio falsa*) and large individual variations are observed. Consequently, so far, from the endocrinological perspective, fetal placental relaxin (RLN) is the only reliable marker of pregnancy in the dog.

Reproductive Cycles During Pregnancy and Pseudopregnancy

Bitches exhibit their first sexual cycle at highly variable ages, depending on the breed, their size and individual predispositions; smaller dogs may reach puberty between 6 to 10 months of age whereas larger breeds may not exhibit their first cycle until the age of 18–24 months.

The domestic dog is an aseasonal (can experience ovarian cycles independently throughout the year) and monoestrous (experience only one estrus or “heat” which is followed by a spontaneous ovulation only once in a breeding season) breeder with an obligatory anestrus in between.

The length of a canine sexual cycle can vary considerably and appears to depend on the breed and genetic predispositions. It can range from 5 up to even 13 months (Concannon, 2011), so in most cases, 2 cycles are observed per year. This does not include the basenji breed, in which the cycle is regulated photoperiodically with the breeding season in autumn in Northern and Southern hemispheres (information on cycles near the equator are missing). The dingo, another representative of the family *Canidae*, is seasonal at both hemispheres, but aseasonal at the equator (Concannon *et al.*, 2009).

The duration of canine pregnancy is approximately 2 months. Anestrus can last for 2–10 months (genetic, individual and breed/size variations all play a role) and ends with increasing GnRH and LH pulsatility (Concannon *et al.*, 2009). Although fertility

decreases with age, sexual senescence in the sense of menopause does not occur in dogs. The optimal breeding age ends at around 6–7 years of age.

Ovarian Cycle

The ovarian cycle in the dog is divided into 4 phases: proestrus, estrus, diestrus (the luteal phase, in some literature frequently designated as metestrus) and anestrus. The length of particular phases is variable (Fig. 1).

It is not known what triggers proestrus and initiation of a new estrous cycle; however, breed, age, environmental factors and genetic background are influencing factors.

Nevertheless, at the end of anestrus GnRH pulses increase, followed by increased LH and FSH pulsatility. The LH pulses appear to be greater than those of FSH (Concannon *et al.*, 2009).

Proestrus and transition to estrus

Proestrus lasts on average 9 days, but can be as short as 2–3 days or as long as 3 weeks. It is characterized by growth of follicles and rising estradiol (E2) concentrations. A bitch becomes attractive to males, however, she does not allow them to mount. Prior to the end of proestrus, E2 starts to decrease and proestrus ends with the LH surge. Estrogens lead to: increased cornification of vaginal epithelium, serosanguinous vaginal discharge caused by predominantly endometrial diapedesis, and anatomically visible edema of the vulva and vagina. The proestrus bleeding typically becomes a more transparent exudate when the cycle enters the stage of estrus. Proestrus and estrus are together referred to as “the heat”.

Anestrus LH levels remain low (<1 ng/mL) with pulse intervals of 4–24 h, occasionally reaching levels between 2–25 ng/mL. Approximately one week before proestrus, LH pulses increase in frequency to every 60–90 min, and average concentrations increase to 3 ng/mL (Concannon *et al.*, 2009). At proestrus, due to negative feedback from estrogens, the pulses and quantity of LH secreted decrease. Its levels increase, however, considerably towards the LH peak, to reach concentrations between 4–40 ng/mL (8–15 ng/mL on average) (Concannon *et al.*, 2009).

As for FSH, it starts to increase at mid- through late anestrus, however without detectable estrogenic activity (the reasons for this remain unclear). A week before proestrus, concomitantly with increasing LH pulsatility, FSH pulse frequencies also rise. Quantitatively however, the FSH increase is less pronounced than that of LH (Feldman and Nelson, 2004).

Estrogen (E2) levels increase with the progression of proestrus, from initial low values of 5–10 pg/mL to the highest preovulatory concentrations of 45–120 pg/mL. At the end of proestrus, E2 levels start to decrease, and the LH peak marking the transition to estrus occurs 1–3 days later. Concomitantly with decreasing E2, P4 levels increase, and both events are needed for the LH surge to occur. By exerting a positive feedback on the hypothalamus and hypophysis, both also lead to enhanced FSH production (Kowalewski, 2017; Concannon *et al.*, 2009; Feldman and Nelson, 2004).

Progesterone: the LH-driven preovulatory luteinization starts during proestrus (Fig. 2(A) and (B)), characterized by increasing P4 even up to 6 days before the LH surge (from basal concentrations of 0.2–0.4 to 0.6–1.0 ng/mL). At the LH surge, P4 rises rapidly, reaching relatively high levels of at least 5 ng/mL (up to 10 ng/mL) at the time of ovulation (which takes place during estrus). The phenomenon of preovulatory luteinization described in the dog by von Bischoff (Bischoff, 1845) is exceptionally strong, and is not observed to this extent in other domestic animal species.

Estrus

Lasts 5–9 days (on average 7 days, but up to 3 weeks, with large variability) (Fig. 2(A) and (B)). Clinically and behaviorally, estrus is characterized by the mounting willingness of a bitch. Endocrinologically, estrus begins 0–1 day from the LH surge. The LH surge is defined as the time when LH for the first time exceeds its basal levels (<200% over the basal values and >50% of the concentrations at the LH peak; (Concannon, 2009, 2011)). The surge is characterized by an initial increase in LH levels over 12–36 h, followed by a 12–24 h decrease, and takes on average 36 h, with a range between 24–72 h (Kowalewski, 2017; Concannon, 2011).

In addition to the initial LH burst, estrus is marked by progressively decreasing E2 concentrations and increasing P4 levels. In particular, following the LH surge, P4 increases strongly towards ovulation. Thus, simplifying, one could say that whereas proestrus is the phase of increasing and high E2 levels, estrus in the bitch is the phase of decreasing E2.

In addition to stimulating the LH surge, the decreasing E2:P4 ratio triggers ovulation (Fig. 2(B)). Ovulation is spontaneous and takes place within 24–72 h after the LH surge (Feldman and Nelson, 2004) and formation of the CL starts immediately thereafter; P4 levels continue to increase, first during the estrus phase and then during diestrus. Furthermore, the decreasing E2/P4 ratio is also responsible for estrus behavior, and bitches typically present “standing heat” with declining E2 levels and with increasing P4 having a positive impact on the length and intensity of estrus behavior (Feldman and Nelson, 2004).

Endocrinologically, estrus ends when E2 levels decrease below 15 pg/mL, and the cycle becomes strongly dominated by P4 (luteal phase) (Feldman and Nelson, 2004).

From the clinical perspective, it has to be emphasized that the estrogen-dependent cornification of vaginal epithelial cells (appearance of anuclear superficial cells or anuclear squames): (i) does not necessarily correlate with the profile of circulating peripheral E2, because (ii) a lag-time of 3–6 days was reported in the response of the vaginal epithelium to circulating estrogens; consequently (iii), the first day when 80–90% superficial keratinized cells are observed can be as soon 6 days before the LH surge, or as late as 4 days afterwards (i.e., at either increasing/maximal, or decreasing E2 concentrations) (Feldman and Nelson, 2004); thus (iv), it is not possible to distinguish late proestrus from estrus based on vaginal cytology; and finally, (v) vaginal cytology, even if

Fig. 2 (A) Schematic representation of changes in estradiol (E2), progesterone (P4), follicle stimulating hormone (FSH), luteinizing hormone (LH), prolactin (PRL), and relaxin (RLN) during pregnant and non-pregnant reproductive cycles in the dog. Placental RLN is the only specific marker of pregnancy. (B) The bottom panel shows a schematic representation of the most important regulatory mechanisms regulating canine luteal function. Timelines are shown in relation to LH peak. COX2 (PTGS2), cyclooxygenase 2; PGE2, prostaglandin E2; PGF2 α , prostaglandin F2 α ; PRLR, PRL-receptor; sER, smooth endoplasmic reticulum (first signs of degeneration within sER can be seen at approximately day 35 after ovulation exhibiting "whorl like" structures, and proceeds further towards fatty degeneration seen around day 45). For both panels detailed explanations are provided in text.

reflects the level of E2-dependent keratinization of the vaginal epithelium, does not allow us to identify the day of the LH peak or ovulation and does not predict the best time for fertilization (Feldman and Nelson, 2004). Even if at “standing heat” up to 100% of superficial cells are cornified, vaginal cytology is not a reliable method for proper timing of a bitch, in particular for artificial insemination.

Diestrus, i.e., luteal phase in pregnant and non-pregnant cycles (Figs. 1 and 2(A) and (B))

Endocrinologically, by definition, diestrus is the phase of the cycle dominated by P4 secretion. Behaviorally, diestrus starts with the end of “standing heat”. Histologically, based on the vaginal epithelial cytology, the onset of diestrus is the day when a dramatic shift from E2 to P4 dominance is observed, i.e., 80–100% of superficial cells appear in estrus vs. the same amount of intermediate or parabasal cells indicating diestrus (Feldman and Nelson, 2004).

From the biological point of view, and for research purposes, based on structural and functional changes observed in ruptured follicles, the time point of ovulation which induces CL formation, is seen as the beginning of diestrus (Kowalewski, 2017).

In non-pregnant dogs, diestrus can last as long as pregnancy (around 60 days) or can extend beyond this time. It ends when peripheral P4 levels decrease below <1 ng/mL and, by definition, the cycle enters the stage of anestrus. This can last even up to 3 months after ovulation. Thus, physiological pseudopregnancy in non-pregnant dogs can exceed by far the length of pregnancy, which is an exception among domestic animal species.

Morphologically, preovulatory luteinization is characterized by strong proliferation and folding in canine preovulatory follicles (Bischoff, 1845). Intense vascularization, morphological and functional changes within the theca interna layers, result in relatively high P4 concentrations at the time of ovulation (see above). Prostaglandins (PGE2 and PGF2 α) appear to be involved in the process of ovulation (Kowalewski, 2017). The local production of endogenous PGF2 α , but not of PGE2, greatly decreases following ovulation (Kowalewski, 2017). Interfering with P4 function at the level of its nuclear receptor (PGR), by application of the antigestagen aglepristone, does not prevent ovulation in dogs (Reynaud *et al.*, 2015).

Following ovulation, further luteinization of theca interna cells and luteinization of the remaining follicular granulosa cells take place, giving rise to the development of a unique population of luteal cells (Kowalewski, 2017). Thus, in contrast to other domestic animal species, in fully developed canine CL, both morphologically and functionally only one population of steroidogenic cells can be identified. Intense vascularization and strong proliferative activity of steroidogenic and non-steroidogenic cellular components take place. The steroidogenic machinery becomes strongly activated and P4 concentrations rise quickly within 15–30 days when CL are fully formed and maximal P4 concentrations of usually 30–35 ng/mL (but even up to 80 ng/mL or higher) are observed. This exposure of the reproductive system to high circulating P4 concentrations is not observed in other domestic animal species. During the early luteal phase, developing CL are, at least to some extent, gonadotropin-independent and prostaglandins, in particular PGE2, appear to be among the most important regulatory factors. Indeed, interfering with prostaglandin synthesis, by administration of a selective cyclooxygenase 2 (COX2/PTGS2) blocker (firocoxib), results in partial suppression of luteal steroidogenic function. More detailed, cumulative descriptions of the underlying regulatory mechanisms can be found in (Kowalewski, 2014, 2017).

Generally, especially following implantation and placentation, numerically but not statistically higher P4 levels are observed in pregnant bitches. The lack of any statistical differences relates most probably to large individual and diurnal variations. Starting at approximately day 25 of the luteal life span, CL become dependent on gonadotropin support, with PRL being the predominant luteotropic factor (Kowalewski, 2017). However, shortly after reaching the highest P4 levels, functional and structural luteal regression starts. Progesterone levels decrease gradually despite increasing availability of hypophyseal PRL and LH.

The slowly ongoing luteal regression is associated with structural and functional changes in steroidogenic cells and remodeling processes within luteal parenchyma. First, around day 35 after ovulation degenerative processes can be seen within smooth endoplasmic reticulum and mitochondria. The appearance of large intracytoplasmic vacuoles further indicates ongoing fatty degeneration (Fig. 2(B)). The steroidogenic machinery slows down, and expression of important luteotropic factors decreases (Fig. 2(B)). Also, the PGE2-driven expression of PRL-receptor (PRLR) diminishes. Whether this is the cause or result of the degenerative process remains unclear.

The similar P4 secretion patterns observed in pregnant and non-pregnant dogs start to diverge just prior to parturition (Fig. 2(A) and (B)), when in pregnant bitches a steep prepartum decrease in P4 levels is observed during prepartum luteolysis, approximately 12–24 h ante partum (prior to any clinical and/or behavioral signs of parturition, like nest building). Concomitantly, circulating levels of PGF2 α of predominantly fetal-placental origin increase, indicating acute luteolytic process (Figs. 3 and 4). In pseudopregnant bitches, the slow luteal regression continues until baseline P4 levels (<1 ng/mL) are achieved at the transition to anestrus. Whereas prepartum luteolysis is associated with massive apoptotic signals, in the CL of non-pregnant bitches apoptotic events are only sporadically observed. As mentioned elsewhere, an intraluteal source of luteolytic PGF2 α can be ruled out in both cases. Interestingly, however, the luteal phase can be terminated by exogenous application of luteolysin, even as early as day 5 of cytologic diestrus, though relatively high dosages and/or repeated treatments are necessary, associated with a high risk of side effects (emesis, diarrhea, panting) (Romagnoli *et al.*, 1991). The constitutive and stable expression of the respective PGF2 α receptor in fully functional canine CL may explain its receptivity to exogenous PGF2 α (Kowalewski *et al.*, 2008). Apparently, therefore, contrasting with the CL of pregnancy, an endogenous source of PGF2 α is missing in pseudopregnant dogs.

The immune system seems to be involved in regulating canine CL function: CD4- and CD8-positive cells, and MHCII-expressing cells, together representing lymphocytes and macrophages, and their immunoactive products (i.e., cytokines) are present in the CL of both pregnant and non-pregnant dogs. As revealed by the transcriptomic approach, the prepartum luteolysis especially appears to be dominated by strong activation of the immune response (Zatta *et al.*, 2017) (Fig. 3).

Fig. 3 Summary of regulatory events involved in termination of canine CL function in pregnant and non-pregnant dogs. Progesterone (P4)-mediated effects indicating the nature of luteotropic actions of P4 in the canine CL are presented, as revealed by the use of an antigestagen (aglepristone) at mid-gestation. Modified after Zatta, S., Rehrauer, H., Gram, A., Boos, A., Kowalewski, M.P., 2017. Transcriptome analysis reveals differences in mechanisms regulating cessation of luteal function in pregnant and non-pregnant dogs. *BMC Genomics* 18, 757.

Cumulatively, contrasting with the PGF2 α -driven, acute (immune) process of prepartum luteolysis, the extended luteal regression observed in pseudopregnant dogs appears to be a passive degenerative process of corpus albicans formation without an (acute) involvement of the immune system. It seems to be modulated, however, by several metabolic, paracrine and most probably autocrine factors, but is apparently devoid of any active luteolytic principle as indicated by the lack of apoptosis. Its inherent life span is not affected by hysterectomy.

Progesterone as a luteotropic factor

The functional withdrawal of P4 caused by an antigestagen results in a pre-term luteolysis/abortion. This is associated with induction of the immune system (a weaker response, however than in natural luteolysis), and suppression of cell proliferation and luteal transcriptional activity (Zatta *et al.*, 2017) (Fig. 3).

Estrogens

E2 is entirely of luteal origin; following the preovulatory peak, E2 continues to decrease, at 15 pg/mL diestrus starts, and the lowest values (8–9 pg/mL) are reached shortly thereafter. Luteal formation and rising P4 are associated with a new increase in E2, starting at approximately day 10, both in pregnant and pseudopregnant dogs (Fig. 2(A) and (B)). This increase is significant, and E2 remains present at average values of 15–40 pg/mL throughout diestrus (varying individually, diurnally and depending on the breed). Importantly, pre-ovulatory E2 concentrations are never reached (Kowalewski, 2017). The secretion pattern of E2 roughly follows that of P4. It decreases towards the end of the luteal life span, further indicating its source within the CL. Therefore, as mentioned elsewhere and contrasting with other domestic animals, there is no prepartum increase in E2.

PRL

This hormone is the predominant luteotropic factor in the dog from approximately day 25 (24–28) onwards after ovulation (Fig. 2(A) and (B)). It is mostly of hypophyseal origin. Interfering with its function (e.g., by administration of the dopamine agonist bromocriptine) during this time leads to premature cessation of luteal function in both pregnant and non-pregnant dogs. These effects can be reversed by PRL but not by LH, which is a weaker luteotropic factor than PRL. The role of PRL is in the maintenance of luteal function rather than in active stimulation of P4 production (PRL administration does not increase P4 levels). Its

Fig. 4 Proposed model of signals participating in feto-maternal communication at the time of prepartum luteolysis in the dog. The key hormonal events associated with the prepartum luteolysis, characterized by decreasing progesterone (P4) and increasing PGF2α levels, are shown in the upper right panel. Photographs represent: (upper panel, left) following removal from the uterus, conceptus (fetus with fetal membranes) is shown before and after the opening of the chorioallantoic sac at mid-pregnancy. Pictures shared by courtesy of Dr. Christine Reich, Justus-Liebig-University Giessen, Giessen, Germany. The macroscopic appearance of the mature canine girdle placenta (*placenta zonaria*) is shown; (middle panel, left) a histological cross-section through the canine utero-placental compartment (full thickness, uterus with adjacent placenta from the middle part of the girdle without the marginal hematoma), shown at low magnification; (middle panel right) a fragment of the canine placenta is presented schematically, decidual cells are the only cells in the canine placenta expressing the nuclear P4 receptor (PGR) and oxytocin receptor (OXTR). The natural- or antigestagen-mediated withdrawal of P4 leads to activation of prostaglandin synthesis (PGF2α) in the fetal part of the placenta (trophoblast). Antigestagens interfere with the biological function of P4 by blocking the function of its receptor (PGR). GR (NR3C1) = glucocorticoid receptor is localized in fetal trophoblast; its expression increases in normal, but not in antigestagen (aglepristone)-induced parturition; (lower panel) depicted are two consecutive microphotographs of canine placenta stained with hematoxylin and eosin (HE; left picture), or vimentin (VIM, right picture; an intermediate filament protein and marker of mesenchymal type cells, stains positively for fibroblasts, endothelial cells, and maternal decidual cells).

concentrations increase significantly in the second half of pregnancy, presumably driven by gestational placental RLN, and reach maximal values prior to term (≈ 50 ng/mL) (Kowalewski, 2017) (Fig. 2(A)). In pseudopregnant dogs, it increases only slightly during the course of diestrus, with maximal values of around 9 ng/mL observed late in diestrus at the time corresponding to parturition. As mentioned elsewhere, due to highly variable concentrations and the occasionally occurring clinical condition of *Lactatio falsa*, circulating levels of PRL do not serve for pregnancy detection. Progesterone withdrawal appears to increase circulating PRL levels.

RLN

RLN increases strongly following implantation and placentation, at approximately 25–30 days after the LH surge (3–4 weeks of gestation) (Fig. 2(A)). It originates mostly in the fetal cytotrophoblasts and exerts local, i.e., intraplacental and uterine, autocrine and paracrine as well as endocrine effects (Nowak *et al.*, 2017). Direct (auto-/paracrine) and indirect (endocrine) luteotropic roles, e.g., through stimulation of hypophyseal PRL secretion, are proposed (Nowak *et al.*, 2018). The highest concentrations of RLN (4–6 ng/mL) are observed 2–3 weeks before parturition and then decrease at parturition. Only low levels of RLN are observed during lactation (0.5–2 ng/mL) for approximately 4–9 weeks (Steinetz *et al.*, 1987). So far, RLN is the only reliable marker of pregnancy in dogs.

Embryo-Maternal Communication, and Establishment and Maintenance of Canine Pregnancy

Following ovulation, immature primary oocytes require 2–3 days (4–5 days after the LH surge) to gain the secondary oocyte developmental stage and acquire the capacity for fertilization. The process of oocyte maturation is still not fully understood, profoundly limiting the success of assisted reproduction techniques. Apparently, P4 acting through its nuclear receptor PGR plays an important role in the maturation process, and when blocked leads to delayed resumption of meiosis and embryonic development retardation (Reynaud *et al.*, 2015).

The “fertilization window”, i.e., the time period when a bitch can be successfully mated is relatively long in the dog (Kowalewski *et al.*, 2015); fertile mating can take place as early as 5 days before ovulation until even 6 days afterwards (all together 11 days) (Fig. 2(A)). This is due to: (i) the long survival time of spermatozoa in the female genital tract with the uterus acting as the main sperm reservoir, and (ii) prolonged survival of oviductal oocytes (7–8 days, including 2 days needed for maturation) (Concannon, 2009; Bischoff, 1845). Embryonic development and oviductal passage are slow in the dog. It takes up to 7–10 days for embryos to reach the uterotubal junction. At this time, their developmental stage can vary widely, being at the early stage of 16 cells or later at morulae or blastocysts. The uterine migration takes 9–10 days; the last blastocysts can hatch as late as day 19 after the LH surge (i.e., approximately 14 days after fertilization). Apposition starts on day 12–14 after fertilization, and uterine implantation and invasion are synchronized, starting at day 17–18 of embryonic life (days 20–21 after the LH surge) (Fig. 2(A)).

Although there is no anti-luteolytic signal in the dog, early embryo-maternal communication does take place and embryos modulate uterine function, facilitating implantation and preventing their own rejection. This contact is initiated prior to implantation and first involves biochemical and functional, rather than morphological, modifications of the uterus, indicating early decidualization processes (Kowalewski *et al.*, 2015). Modification of matrix assembly and immunomodulatory effects are observed, as indicated by transcriptomic studies (Graubner *et al.*, 2017a; Kowalewski *et al.*, 2015). More detailed studies regarding involvement of the immune system in these processes are presently in progress.

The factors produced by embryos relating to implantation are not yet fully described (Kowalewski *et al.*, 2015). In addition to immune system-derived factors observed in other species, PGE2 appears to play an important role: (i) it is expressed by embryos and exhibits higher levels in hatched than in unhatched blastocysts prior to implantation, (ii) expression of the PGE2 synthesizing enzymes and the respective PGE2 receptor (EP2) is elevated in the early pregnant uterus, and (iii) PGE2 exerts a strong decidualization effect on canine stromal cells (Graubner *et al.*, 2017b).

The presence of attaching conceptuses induces the first morphological changes in the uterus. The subepithelial morpho-functional decidualization of maternal endometrial stromal compartments starts and decidual cells begin to develop (Graubner *et al.*, 2017b). Importantly, and in contrast with humans, the decidualization process in the dog is not driven by circulating P4 (even if it is exceptionally high), but similar to rodents, by the presence of embryos (Graubner *et al.*, 2017b). Following implantation, maternal stromal cells further develop into placental decidual cells and become an integral part of the placenta. These are the only cells of the canine placenta expressing the nuclear P4 receptor (PGR) and oxytocin receptor (OXTR). As shown in ovariectomized bitches, P4 alone is enough for establishment and maintenance of pregnancy in previously estrogenized bitches (Concannon *et al.*, 2001).

Termination of Canine Gestation, and the Prepartum Luteolytic Cascade

The canine placenta is classified as an *endotheliochorial* (possessing strongly invasive trophoblast, *deciduata*) *zonary* placenta, i.e., forming a girdle of chorionic villi around the middle of the chorionic sac (Fig. 4). It develops glandular chambers (greatly enlarged superficial endometrial glands, also called the *spongy zone*). These are 1–2 mm thick and separate the placental labyrinth from the connective tissue layer covering the deep uterine glands. They continue to grow until day 40 of gestation, from then on fully developed utero-placental compartments are established.

The prepartum increase in PGF2 α seems to originate in the fetal part of the placenta (trophoblast), where the entire machinery producing PGF2 α is localized and is concomitantly strongly activated. The underlying mechanisms, at least to some extent, are P4-dependent, because interfering with PGR function in decidual cells by administration of antigestagens also induces synthesis of PGF2 α in neighboring fetal trophoblast cells (Fig. 4). Thus, maternal stroma-derived decidual cells appear to be involved in the underlying P4-dependent feto-maternal cross-talk leading to the prepartum release of PGF2 α . In both situations, i.e., during normal and induced parturition, expression of the OXTR increases in these cells (Fig. 4). Based on our own data, including transcriptomic analyses (unpublished), the functional involvement of the immune system during maintenance and termination of pregnancy is under discussion (Fig. 4).

Cortisol

The increased presence of cortisol in the maternal circulation pre-partum has been described as being of an “erratic nature”, i.e., it is observed occasionally, but is not required for normal parturition. The circulating cortisol levels, however, do not have to fully mirror local concentrations of glucocorticoids. Therefore, local effects cannot be excluded. The increased placental expression of glucocorticoid receptor (GR/NR3C1) is, however, not needed to induce prepartum PGF2 α synthesis in the dog. Being localized in fetal trophoblast, its expression increases significantly in normal but not in induced parturition (Kowalewski, 2017) (Fig. 4). Importantly, clinical application of glucocorticoids (dexamethasone) does not seem to mimic the natural prepartum signaling cascade, since prolonged treatments, on average over 8 days, are needed for pregnancy termination, associated with side effects like polydipsia and polyuria (Wanke *et al.*, 1997).

Closing Remarks

As shown herein, canine reproductive cycles indeed appear to be quite unique among domestic animal species. Driven by the same goal of reproductive success, dogs present different regulatory strategies. Many biological, clinical and breeding questions remain unsolved. Thus, for example, knowledge regarding mechanisms involved in termination of anestrus, the regulation of oocyte maturation, resumption of meiosis and early embryonic development, needs to be improved. So far, in vitro fertilization of in vivo matured oocytes has been reported, but obtaining mature oocytes post-ovulation is tedious and erratic. As for in vitro oocyte maturation, the efficiency is still low. Better understanding of mechanisms involved in the establishment and maintenance of pregnancy could be helpful in understanding the pathogenesis of some frequently occurring uteropathies and could lead to development of better clinical protocols, providing better assistance for patients during maintenance and termination of canine gestation.

Female Cat Reproduction

Janine L Brown and Pierre Comizzoli, Smithsonian Conservation Biology Institute, Front Royal, VA, United States

Introduction

The domestic cat is one of the world's most popular companion animals, in addition to playing an important role in biomedical research, contributing to the fields of genetics, fertility, developmental biology, neurophysiology, cancer, immunology, and infectious disease. Being obligate carnivores, cats share the instinct to hunt prey. With the exception of lions, felids are solitary and do not live in socially structured adult groups. They are generally adaptable to a wide range of environments, and are found on every continent except Antarctica. Of the 41 known wild cat species, at least two-thirds are threatened or endangered with extinction in some part of their natural range. Felids are placed into small (<6.5 kg, 45% of species), medium (7–20 kg, 35%) and large (35–135 kg, 20%) body weight categories. The major causes of wild population declines are habitat loss and fragmentation, human-animal conflict, and for some species, poaching for pelts and traditional medicines. Yet, despite a long history in captivity, a significant challenge continues to be determining how to manage these generally secretive animals in environments that allow them to thrive and reproduce. Even in relatively naturalistic enclosures, reproduction in captive felids remains poor, with the exception of some of the *Panthera* species. As reproduction is the essence of species survival, an understanding of how female cats reproduce can contribute to their sustainability and conservation.

Domestic Cat

Reproductive Anatomy

The vulva is located just below the anus and is followed by a 10–30 mm vestibule ending with a narrow ring-like structure (close to the urethra). The straight vagina is long (up to 70 mm) and ends with a short cervix that has a dorso-cranial opening. The small uterine body is partially divided internally by a septum leading to two horns (50–70 mm long) that are suspended dorsally by the mesometrium. After the utero-tubal junction, the long and convoluted oviducts are lateral to the ovaries and terminate into an ovarian bursa formed by the mesosalpinx. The ovaries (10×5 mm) are caudal to the kidneys and attached proximally by the suspensory ligament and dorsally by the mesovaria.

Sexual Maturation and Seasonality

The female reaches puberty at 5–12 months of age, at approximately 75% of adult body weight, with some dependence on season of birth and growth rate (Tsutsui and Stabenfeldt, 1993; Wildt *et al.*, 1998). In general, short-haired breeds reach puberty earlier than long-haired cats. The domestic cat is seasonally polyoestrous under natural photoperiods, but will cycle year-round when housed on a 12–14 h light cycle (Shille *et al.*, 1979). Cats are long-day breeders, so ovarian activity is reduced during winter and resumes after exposure to increasing daylight (February or March through September in the northern hemisphere). Because seasonality is affected by photoperiod, geographic latitude influences degree of seasonality. Melatonin regulates photoperiod-induced seasonality in the cat, with concentrations being highest during the dark phase (Leyva *et al.*, 1989). Females appear to exhibit a graded response to melatonin, with greater follicular suppression occurring as the daily duration of melatonin elevation is increased (Leyva *et al.*, 1989; Graham *et al.*, 2004).

Gametogenesis

Like in many other mammal species, the cat ovarian follicle is composed of an oocyte surrounded by granulosa cells. Morphology changes as the oocyte grows and the surrounding cells differentiate during folliculogenesis. After the migration of primordial germ cells into the gonad, the early stages of gametogenesis begin during the second or third week of fetal development. There is then a large number of primordial follicles located throughout the ovarian cortex, beneath the tunica albuginea (Bristol-Gould and Woodruff, 2006). In addition to follicles, the ovarian cortex contains stroma cells and an extra-cellular matrix that plays a role in the regulation of the early stages of folliculogenesis. The ovarian medulla is mainly comprised of blood vessels dispatched to the rest of the gonad.

Primordial follicles have an oocyte ranging from 20 to 30 μ m in diameter directly surrounded by flat cells. After activation, which is controlled by intra-ovarian factors and not gonadotropins, primordial follicles transition to primary follicles containing oocytes ranging from 30 to 50 μ m in diameter and a single layer of cuboidal granulosa cells. At this stage, the zona pellucida is easily detected, in addition to a basement membrane separating the surrounding layer of granulosa cells from the ovarian stroma (Bristol-Gould and Woodruff, 2006). Primary follicles grow into secondary follicles that vary greatly in size due to multiple layers of granulosa cells, ranging from 100 to 400 μ m, and contain oocytes ranging from 40 to 75 μ m in diameter. At least two, but usually more layers of granulosa cells are apparent and a theca cell layer is assembled on the outer side of the basement membrane. The next stage is the early/small antral follicle that is similar in diameter at the onset of antral formation to secondary follicles. Antral follicle

growth (from 300 to 1000 μm in diameter as follicular fluid accumulates) and cell differentiation are dependent on gonadotropins. While oocytes are approximately 75–90 μm in diameter, these antral follicles are surrounded by two to three layers of thecal cells. Large antral follicles are the ultimate stage that grow to 2–3 mm in diameter and contain intact mural and cumulus granulosa cell layers, many theca cell layers, a large antrum, and an oocyte. Not all ovarian follicles reach that stage, however, as more than 60% will undergo atresia. At the final stage, the oocyte diameter is $\sim 100 \mu\text{m}$ (without the zona pellucida) and the germinal vesicle (nucleus at the Prophase I of the meiosis) is larger than in other species (35–40 μm diameter) (Comizzoli *et al.*, 2011). The oocyte cytoplasm is dark because of the high concentration in lipid droplets. Preovulatory follicles and the enclosed oocytes require an adequate luteinizing hormone (LH) stimulus to trigger oocyte maturation (resumption of the meiosis to the metaphase II stage) and ovulation.

Ovarian Cycle

There are four phases of the domestic cat ovarian cycle: proestrus, estrus, diestrus, and anestrus (or interestrus). Based on regular fluctuations in estrogens, unbred domestic cats have an estrous cycle length of ~ 2 weeks, with estrus lasting 3–7 days.

Proestrus

The proestrus phase lasts for 1–2 days, but the signs are not always obvious. This phase consists of the presence of ovarian follicles (1–2 mm diameter) and synthesis of estradiol-17 β that circulates at high concentrations (Shille *et al.*, 1979). The female demonstrates behaviors, such as vocalizing, rubbing the head and neck against objects, and rolling on the ground. Occasionally, there is interest in males, but it excludes copulation.

Estrus

Females are in estrus for 3–16 days, during which time they display clear mating behaviors: for example, calling, rolling, urinating. Females assume a lordosis posture, head and front legs down, rump held high, during mating. Estrous behavior rapidly follows increased circulating estradiol-17 β associated with advanced follicular development (Shille *et al.*, 1979). Estrus is characterized by permitting male mounting and coitus, and usually vocalization, lordosis, and foot-treading. Behavioral signs are strongest in association with peak estrogen secretion around Day 3 (Tsutsui and Stabenfeldt, 1993). Estradiol-17 β usually remains above 20 pg/mL of serum (mean range, 25–100 pg/mL) during estrus (Fig. 1). Distinct pre-ovulatory follicles (>2 mm diameter; usually one to four follicles/ovary) protrude slightly above the ovarian surface. Neither coitus nor ovulation affects the duration of elevated estradiol-17 β or estrus. Frequent matings are usually needed to stimulate sufficient LH to cause final follicular maturation and ovulation, which occurs 24–48 h post-coitus depending upon the time of mating onset (Fig. 1). The ovulatory LH surge occurs within minutes of copulation, peaks in a few hours and returns to baseline within 4–16 h (Shille *et al.*, 1983; Johnson and Gay, 1981). If ovulation is not induced during estrus, the queen will enter an anovulatory phase, referred to as anestrus or interestrus, and go into proestrus again. If the mated queen does ovulate, diestrus ensues, which can proceed to gestation if conception occurs or to a nonpregnant luteal phase if the mating is infertile.

The cat is typically classified as an induced ovulator; however, spontaneous ovulations occur in many laboratory-maintained females, often frequently, depending upon the individual, housing conditions, proximity to a male, and possibly genetics (Concannon, 1991). Reflex ovulations depend on coitus-induced neuronal stimulation of the medial basal hypothalamus, release of gonadotropin-releasing hormone (GnRH), and a subsequent LH surge from the pituitary (Fig. 1). Cats copulate frequently

Fig. 1 Schematic diagram of circulating estradiol-17 β (dashed line), LH (dotted line) and progesterone (solid line) concentrations during the estrous cycle and post-ovulation in domestic cats. Arrows designate mating.

during estrus (as often as 36 times within 36 h), and early matings serve more to finalize folliculogenic events (oocyte maturation and release) than to ensure the presence of many sperm. With frequent mating, blood LH surges within 8 h of coital onset and then gradually declines during the next 20–24 h (Fig. 1). Such LH surges are sufficient to cause final follicular maturation, with ovulation then occurring at variable time after first breeding. Queens mated three times/day beginning on Day 1 of estrus require ~48 h to ovulate, whereas cats mated initially on Day 2 of estrus ovulate within 30–36 h. Matings starting on Day 3 or 4 complete ovulation within ~32 h. Pre-ovulatory follicles (2.5–3.5 mm diameter) become vascularized, develop a central hyperemic stigma, and release follicular contents onto the ovarian surface, with a slight inward collapse of the follicular apex. Ovulation is all-or-none because follicle number before mating corresponds to corpora lutea (CL) number after coitus (~1–4 CL/ovary). If mating is limited to one copulation, neither an LH surge nor ovulation usually occurs. This neuroendocrine pathway can become refractory because copulations on consecutive days result in fewer LH surges of lower amplitude (Fig. 1). The last copulations on a given day of unrestricted matings fail to elicit increased LH, and suppression may persist for 48–72 h. However, injecting GnRH can induce a pronounced LH surge, indicating that decreased responsiveness is caused by depleted hypothalamic GnRH or feedback inhibition of GnRH on further hypothalamic GnRH release.

Diestrus

Ovulating queens enter diestrus, a phase in which the queen no longer displays estrual postures and is unresponsive to the male. There is vacuolation (luteinization) of granulosa and theca interna cell cytoplasm in corpora hemorrhagica as early as 64 h after first mating. By 100 h (48–72 h after ovulation), CL develop as raised, reddish-orange structures with polygonal cellular morphology (Fig. 2), each reaching maximal size within 10–16 days. Circulating progesterone increases above baseline (<1 ng/mL) ~76 h after first mating (~40 h after ovulation), increasing to 25–90 ng/mL within 4–22 days. In response to rising progesterone, uterine glandular epithelia show increased cell height and cytoplasmic vacuolation (Fig. 2). Luteal progesterone and LH receptor content are static for the first 100 h and then increase in parallel with peripheral progesterone (Fig. 2). Rapid progesterone increases beginning at 76 h reflects accelerated synthesis within the CL, with LH playing a luteotropic role. Progesterone is elevated for 36–38 days in nonpregnant cats, after which CL gradually regress to form persistent luteal scars. Many females then reinstate estrous cyclicity within 7–14 days. The interval of elevated progesterone during a sterile luteal phase (~36 days) is shorter than that during pregnancy (63–67 days) (Fig. 3). Though often referred to as ‘pseudopregnancy’, the nonpregnant luteal phase in the cat is not associated with maternal behaviors or mammary gland development.

Anestrus

Anestrus (or interestrus) is a phase of reproductive dormancy characterized behaviorally by indifference or active resistance to sexual advances. Mature ovarian follicles undergo atresia, and peripheral estradiol-17 β is at nadir. The normal interestrus phase in cycling, nonovulating females ranges from 7 to 21 days. Seasonal anestrus also is observed in cats exposed to natural photoperiods, with reduced ovarian activity during short days. However, many cats appear to cycle year-round.

Conception, Pregnancy and Parturition

Multiple oocytes are ovulated at the metaphase II stage, are fertilized in the proximal oviduct, and most reach the 2-cell stage by 64 h after first breeding. Blastomeres then cleave every 24 h (Fig. 2). Embryos undergo compaction at the morula stage while passing through the utero-tubal junction and form early blastocysts 124–148 h after first mating. This timing correlates with the decline of circulating estradiol 17 β and rapidly increasing progesterone. This period also corresponds with pronounced morphological changes in the uterine histology (Fig. 2). Cat embryos then migrate between uterine horns to evenly distribute fetuses. After zona lysis, implantation and the beginning of the formation of a zonary endotheliochorial type placenta begins on Day 13–14 post mating.

Temporal progesterone profiles after ovulation and through the demise of the CL vary among individuals, so progesterone concentrations cannot be used as a reliable indicator of pregnancy during the first 36 days after ovulation. Luteal LH receptor and progesterone content increases after 100 h in parallel with the rise in circulating progesterone (Fig. 2; Roth *et al.*, 1995). After ovulation, serum estradiol-17 β periodically fluctuates above basal levels, indicating steroidogenic activity occurs even during gestation. Estrogens increase significantly and steadily during the latter half of gestation, with a distinct surge occurring about a week before parturition (Schmidt *et al.*, 1983). Progesterone is produced primarily by CL during the first 40–45 days of pregnancy. Ovariectomy does not induce abortion, so the placenta has been credited with producing progesterone during the last 3 weeks of pregnancy. During the second half of pregnancy, estradiol-17 β periodically fluctuates above basal levels, indicating that there are continuous waves of follicular development. A distinct estradiol-17 β surge occurs 8 or 9 days before parturition. Queens occasionally mate during pregnancy, with superfetation a possible but infrequent occurrence. Peripheral prolactin increases about Day 35 of pregnancy, plateaus 2 weeks later, is maintained through parturition and the first 4 weeks of lactation, and is at nadir shortly after weaning. Prolactin may be luteotropic in the pregnant cat because administering the anti-prolactin, dopamine antagonist, cabergoline, at 30–40 days reduces progesterone to baseline and causes fetal absorption or abortion (Johnson and Gay, 1981; Jochle and Jochle, 1993). Peripheral relaxin from the fetoplacental unit increases beginning about Day 25 of gestation to help soften pelvic connective tissue, reaches a plateau 5–10 days later and then declines to baseline at parturition (Stewart and Stabenfeldt, 1985). Progesterone declines slowly, beginning ~30 days into gestation, returning to nadir on, or shortly after, the day of parturition. Circulating prostaglandin F $_{2\alpha}$ from the fetoplacental unit and endometrium increases at ~Day 30, plateaus at Day 45, and surges

Fig. 2 Composite diagram of *in vivo* embryogenesis, endocrine profiles, and histological traits in natural estrus and mated domestic cats.

Fig. 3 Serum progesterone profiles during a pregnant (solid line) and nonpregnant (dashed line) luteal phase in the domestic cat.

just at the end of gestation to facilitate parturition (Tsutsui and Stabenfeldt, 1993). This hormone has a direct luteolytic effect and can induce abortion and fetal expulsion if administered after Day 30 of gestation (Versteegen *et al.*, 1993).

Diagnosing pregnancy based on progesterone analysis during the first half of gestation is not effective because luteal phase profiles are similar (Fig. 3). However, because the nonpregnant luteal phase is shorter, it is possible to diagnose pregnancy if progesterone is still elevated after ~40 days post-mating. Relaxin and prolactin measured in serum or plasma also are diagnostic of pregnancy after mid-gestation because neither are secreted during nonpregnant luteal phases. Though most effective using serum or plasma, commercial canine relaxin immunoassays have been used to diagnose pregnancy during late pregnancy in domestic cat using urine (de Haas van Dorsser, 2006, 2007). Recently, an immunoassay for a prostaglandin F_{2α} metabolite in domestic cat urine and feces has been shown to be diagnostic of pregnancy (Dehnhardt *et al.*, 2012). Prostaglandin F_{2α} in circulation is quickly metabolized to 13,14-dihydro-15-keto-PGF_{2α} (PGFM) in the lungs, and has a longer half-life in blood than its original compound. In dogs, PGFM is elevated 2–4 days before birth (Luz *et al.*, 2006), but in domestic cats, it increases several weeks before parturition.

Kittens are weaned after ~8 weeks, thus permitting a female to produce up to three litters per year. Domestic cats have long served as the model species for developing assisted reproductive techniques in wild felids (Howard *et al.*, 1992, 1996).

Non-Invasive Steroid Hormone Monitoring

A series of studies in the 1990s on domestic cats paved the way for development of noninvasive techniques to monitor reproductive hormones in felids. Unlike other taxa, where steroids typically are found in both urine and feces, in cats the main route of steroid excretion is the feces. For example, after injection of radiolabelled estradiol-17β and progesterone into domestic cats, 95% of metabolites were excreted in feces within 1–2 days (Shille *et al.*, 1990; Brown *et al.*, 1994). High performance liquid chromatography, gas chromatography/mass spectrometry and immunoreactivity analyses demonstrated that: (1) fecal estrogens consist primarily of unconjugated and conjugated (3-sulfate, 17α-sulfate and 17β-sulfate) estradiol, with minor amounts of estrone and estriol; and (2) progesterone is metabolized and excreted as mostly polar compounds (>75%), presumably conjugates, and some unconjugated pregnanes. Steroid metabolites can be extracted from feces by boiling, vortexing or shaking in combinations of organic solvents (e.g., ethanol, methanol), usually containing at least 10% water or buffer to assist in recovery of conjugated steroids. A number of variables can affect measures of steroid metabolites: age of sample after defecation, environmental exposure, sample volume and consistency, and sample homogeneity. These effects are not always consistent between species or hormones, necessitating that each assay and fecal handling technique be properly validated using both laboratory and biological tests. As discussed below, noninvasive fecal monitoring has played a key role in our understanding of the wide range in reproductive patterns across felid species.

Wild Felids

General Biology

Information on sexual maturity, estrous cycle characteristics, gestation length, and litter size of the 41 currently recognized nondomestic felids (Kitchener *et al.*, 2017) is summarized in Table 1. Because of their secretive nature, limited information is

Table 1 Life history and reproductive characteristics of Felidae

Common name	Genus/species	Geographic range	Sexual maturity (months)	Estrous cycle (days)	Estrus (days)	Gestation (days)	Litter size (range)	Seasonal breeder
African golden cat	<i>Caracal aurata</i>	West/Central Africa	11	nd	nd	75–81	1–2	nd

^aAt least some hormonal data are available (serum and/or fecal metabolite analyses).^bSeasonality occurs in some populations but not others.Source: Based on Kitchener, A.C., Breitenmoser-Würsten, C., Eizirik, E., *et al.*, 2017. A revised taxonomy of the Felidae. The final report of the cat classification task force of the IUCN/SSC Cat Specialist Group. Cat News Special Issue 11, pp. 1–80.

available on the biology of felids in situ. Most is based on studies of captive individuals. Hormone data are available for about 23 species, mostly through fecal steroid metabolite analyses, although much are based on only one or two animals and for short durations. For some species, however, there is almost no reproductive information: Andean mountain cat, Bornean bay cat, Chinese mountain cat, flat-headed cat, Iriomote cat, kodkod, Southern tigrina, Sunda clouded leopard and Sunda leopard cat.

Reproductive tract and ovarian anatomies described so far are similar to the domestic cat and only vary in size proportionally to the body weight of the species.

Ovarian Cycle and Seasonality

Folliculogenesis is not different from what has been described in the domestic cat. Also, similar to the domestic cat, estrous cycles of wild felids are characterized by periods of high (estrus) and low (interestrus) estrogen concentrations (**Fig. 4**). Based on estrogen analyses, demographic data or behavioral observations, estrous cycle lengths range from less than a week to just over a month across species, with estrus ranging from 1 to 12 days (**Table 1**). Wide variability in reproductive data are due to limited sample collection and/or assessment of only a few individuals/species. Endocrine data are the most accurate for defining reproductive cycle characteristics because of the high prevalence of silent estrus. Most wild felids mate frequently; thus, it has been assumed they too are strictly induced ovulators. However, we now know that felids exhibit a range of ovulatory patterns, from almost exclusively induced to varied combinations of induced and spontaneous (e.g., **Fig. 5**). These differences occur not only across species, but also between individuals within a species (**Brown, 2006, 2011**). Thus, spontaneous increases in progestagens after estrogen surges are nonexistent or rare in species like the tiger, puma, snow leopard, cheetah, tigrina, jaguar, sand cat, lynx and ocelot; occur at least occasionally in lion, leopard, black-footed cat, Pallas' cat, bobcat, and fishing cat; and are quite common in the clouded leopard and margay. In some species, non-mating induced ovulations are more prevalent when females are housed together, whereas in others they also can occur in singletons. Thus, within this taxon ovulatory mechanisms vary, regulated to a greater or lesser degree by species and perhaps individual-specific responses to physical and/or psychosocial stimuli.

Seasonality of reproduction is specified in **Table 1**. At least 13 species exhibit seasonal breeding in the wild and/or captivity, whereas for 15 others, births have been observed in every month of the year. Ten of these species have no data on seasonality of breeding or births. Seasonality of reproduction is controlled in part by photoperiod, similar to that for the domestic cat. For example, clouded leopards exhibit anestrus in the late summer/early fall both in northern latitudes and in Asia, but if housed indoors with exposure to 12 h of continuous artificial light per day, females will cycle year-round (**Brown et al., 1995**). Pallas' cats have the shortest breeding season, with ovarian activity observed only for ~3 months of the year (Jan-Mar) (**Brown et al., 2002**). Sudden transitions to 'long days', as in a zoo lights festival, can stimulate premature follicular steroidogenesis in highly seasonal cat species, and negatively impact reproduction (**Brown et al., 2002**). A few species, like leopard cat, sand cat and serval, exhibit 'variable' seasonal reproduction that is linked to environmental conditions or prey availability rather than being restricted to specific months.

Many felids exhibit periods of follicular inactivity that are not associated with season. Cycles are observed in every month of the year, but not continuously for many individuals (e.g., cheetah, ocelot, fishing cat) (**Brown, 2006, 2011**). There is no common cause of ovarian acyclicity in felids. Suppression of estrous cyclicity in cheetahs (**Brown et al., 1996**) and Canadian

Fig. 4 Comparative profiles of fecal estrogens (dashed lines) and progestagens (solid lines) in the cheetah (top panel), tigrina (middle panel) and lion (bottom panel) showing lack of spontaneous ovulations.

Fig. 5 Concentrations of fecal estrogens (dashed line) and progestagens (solid line) in the clouded leopard during cycles with and without spontaneous ovulations. Non-mating induced ovulations are indicated by the stars.

lynx (Fanson *et al.*, 2010) often occurs when females are housed together, and in cheetahs, separation of pairs results in normal cyclic ovarian activity (Wielebnowski *et al.*, 2002). In ocelots, ovarian inactivity was associated with poor husbandry management, and was ameliorated by addition of enrichment items and hiding places (Moreira *et al.*, 2001). For many species, however, causes of ovarian acyclicity remain elusive.

Compared to other felids, ovarian function in lynx differs in many aspects. For one, estrogen and progestagen immunoassays are not effective in clearly identifying ovarian follicular and luteal function, respectively, despite excretion of native hormone into urine and feces (Fanson *et al.*, 2009; Dehnhard *et al.*, 2008). Clear cyclic estrogen patterns even with daily collections are not evident, nor are progestagens effective at diagnosing pregnancy. Instead, overall estrogen concentrations increase throughout the breeding season, regardless of whether mating or pregnancy ensues. Iberian and Eurasian lynx are strictly seasonal breeders with, normally, a single ovulatory cycle, and thus are the only monovulatory felids (Fanson *et al.*, 2009; Dehnhard *et al.*, 2008). Another peculiarity is the presence of persistent CL and elevated progestagen concentrations, which are maintained for at least 2 years after ovulation, regardless of origin (pregnant, pseudopregnant), possibly to prevent continued follicular activity (Jewgenow *et al.*, 2014). Lynx also are unusual in that there is significant co-excretion of estrogen and progestagen metabolites in feces (up to $r=0.8$), suggesting some estrogen immunoreactivity may, in fact, be of luteal origin (Dehnhard *et al.*, 2008). Finally, continued progestagen production postpartum is observed due to the presence of active CL during the lactational anestrus period (Göritz *et al.*, 2009; Dehnhard *et al.*, 2008; Jewgenow *et al.*, 2014). This activity may act to support lactation, prevent new follicular cycle activity, and thus restrict the breeding season to midwinter. Though not as extensively studied, the Canadian lynx appears to share many of these traits, including persistent CL across cycles (Fanson *et al.*, 2010). The bobcat is the only cat in the lynx genus that is seasonally polyestrous, but they too exhibit CL that persist in subsequent cycles (Jewgenow *et al.*, 2014).

Pregnancy and Post-Partum

Progestagen concentrations during pregnant and nonpregnant luteal phases in nondomestic cats are quantitatively similar, as in the domestic cat (e.g., Fig. 6). In felids where comparative data are available, length of the non-pregnant luteal phase is about one third to one half that of pregnancy (Brown, 2006, 2011). There is an interesting species difference in estrogen excretory patterns throughout gestation, with concentrations increasing after mid gestation in the cheetah, Pallas' cat and fishing cat, similar to the domestic cat, but remain stable throughout pregnancy in the clouded leopard and tiger (Brown, 2011). Relaxin measured in urine using a canine RIA can diagnose pregnancy after mid-gestation in leopards (de Haas van Dorsser, 2006). A simple strip test from the same company (Witness Relaxin[®]) was moderately effective in diagnosing late pregnancy in Iberian lynx urine samples, but only if concentrated by ultrafiltration and brought up in serum (Braun *et al.*, 2009). More recently, PGFM has been found to increase in urine and/or feces in the weeks before parturition in several nondomestic cat species/subspecies (sand cat, African wildcat, Siberian tiger, North Chinese leopard, leopard cat, ocelot, serval, tigrina, caracal, fishing cat, Geoffrey's cat, Iberian and Eurasian lynx, cheetah, puma), thus providing a clear signal differentiating between pregnant and pseudopregnant luteal cycles (Dehnhard *et al.*, 2012, 2014, 2015). By contrast, only moderate increases in PGFM during gestation were found in Indochinese tiger and Persian leopard.

Fig. 6 Concentrations of fecal estrogens (dashed line) and progestagens (solid line) during pregnant and nonpregnant luteal phases in a lion.

Biomedical Science and Conservation

Domestic cat females have been used as animal models in reproductive science for decades, and compared to laboratory rodents, they offer many advantages because of greater similarities in follicular anatomy and gamete biology with women. Fertility preservation approaches developed in the female cat have direct applications to human reproductive medicine (Comizzoli *et al.*, 2011). Of course, the domestic cat also has been a critical model to better understand the reproductive biology of wild counterparts.

Felids express marked variations in reproductive mechanisms among species. Identifying the type of ovulation (induced versus spontaneous) and effect of seasonality on reproduction for each species is particularly important as these two characteristics impact both natural and assisted breeding efforts. The ability to easily and safely assess reproductive status through noninvasive means is vital to our understanding the causes of poor fertility of cats in natural breeding situations and in response to assisted reproductive procedures. In the nearly three decades since fecal steroid techniques were developed for wild felids, over 300 papers have been published that describe gonadal cycle patterns for just over half of the species. Thus, an impressive endocrine database now exists, and hormone monitoring has played a major role in the breeding management of many felid species.

One of the most useful benefits of steroid metabolite monitoring has been assessing causes of poor fertility in response to assisted reproductive procedures, like artificial insemination and embryo transfer, allowing these tools to more reliably contribute to species propagation. A high priority today is developing ovulation induction protocols that result in consistent responses, without ovarian hyperstimulation, to provide an optimal maternal environment for fertilization and embryo development. Along with this effort is the need to control the reproductive cycle, including down-regulating endogenous ovarian activity and synchronizing estrus (Pelican *et al.*, 2006; Swanson, 2006). More reliable tests for diagnosing pregnancy are still needed, preferably ones that are noninvasive and applicable across all species. Developing optimal protocols for breeding cats, by both natural and assisted means, are key to conserving and managing endangered populations.

Reproductive Toxicity of Environmental Contaminants in the Female

Warren G Foster, McMaster University, Hamilton, ON, Canada

Introduction

It has been estimated that there are more than 80,000 chemicals in commercial use and thus assessing risk associated with potential human exposure is a daunting task. Human exposure to chemical contaminants has been widely documented through biomonitoring and epidemiological studies. Among the many pathological and iatrogenic conditions that jeopardize reproductive function, chemical exposures have been associated with adverse health effects on the structure and function of the reproductive tract in females including: altered timing of pubertal onset, disruption of menstrual cycle function (Cooper et al., 2005; Jukic et al., 2015), sub-fertility and impaired response to ovulation induction (Alviggi et al., 2014; Petro et al., 2012; Tanrikut et al., 2014), ovarian cancer (Langseth and Kjaerheim 2004), increased time to achieve pregnancy (De Cock et al., 1994), spontaneous abortion (Arbuckle et al., 2001; Korrick et al., 2001), polycystic ovarian syndrome (PCOS) (Kandaraki et al., 2010; Kandaraki et al., 2011; Rutkowska and Rachon 2014) endometriosis (Cobellis et al., 2003; Kim et al., 2011; Louis et al., 2005; Reddy et al., 2006) and earlier age at menopause (Grindler et al., 2015). While the literature demonstrates numerous examples of potential associations between environmental contaminant exposure and adverse reproductive health outcomes, many others have been unable to show similar associations (Foster et al., 2008; Sadeu et al., 2010; Sifakis et al., 2017), hence links with adverse reproductive health outcomes in females remains equivocal. Although potential effects in the general population remains uncertain, the strongest evidence and potential for modifiable risk is limited to occupational groups (e.g. farmers) or specific populations whose lifestyle, such as sport fishing, presents risks for high exposure to known reproductive toxicants (Mendola et al., 2008). Furthermore, the mechanisms underlying these adverse effects are poorly defined. For many commercial chemicals though, there is an absence of evidence of human exposure, and thus causal associations are difficult to establish. Consequently, improved methods are necessary to assess reproductive health in women for occupational screening programs and epidemiological studies.

Although the literature is generally equivocal on the relationship between exposure to environmental contaminants and adverse reproductive outcomes in humans, animal studies support the above associations. Environmental contaminants inhibit germinal nest breakdown and induce oocyte aneuploidy (Hunt et al., 2003; Susiarjo et al. 2007), produce anomalies of reproductive tract development (Flaws et al., 1997; Gray et al., 1997; Gray and Ostby 1995), disrupt ovarian steroidogenesis (Craig et al., 2011), decrease ovarian follicle counts (Borgeest et al., 2002; Borman et al., 2000; Peretz et al., 2012), and impair fertility. Consequently, animal studies have become indispensable in furnishing the scientific community with experimental evidence central to establishing biological plausibility. In order to enhance the pace for screening chemicals, reduce the numbers of animals required for testing, and to define mechanisms of action (MOA), sensitive screening methods and innovative techniques are required to assess reproductive hazards.

Biomarkers of Female Reproductive Function

In women's health, clinical markers of follicle development, oocyte health, and embryo quality, as well as for the diagnosis of endometriosis, polycystic ovarian syndrome (PCOS), and ovarian cancer are either non-existent or sub-optimal. Assessing reproductive fitness in a population exposed to environmental contaminants remains a challenge owing to the relative paucity of sensitive and specific clinical markers of adverse effects. While menstrual cycle irregularity, difficulty conceiving, and repeated spontaneous abortion are all indicators of reproductive dysfunction, none are rare or unique to chemical exposures. Thus, ability to assess reproductive health in women and determine the impact of environmental contaminants in exposed populations is limited. The search for novel biomarkers of reproductive health and disease therefore continues to be a high priority research need in toxicology and reproductive medicine.

Circulating concentrations of follicle stimulating hormone (FSH) together with antral follicle counts is often used to assess ovarian reserve and detect effects of advanced maternal age. However, these parameters of reproductive fitness are of limited value in women under 40 years of age and the impact of exposure to environmental contaminants on them is poorly defined. Serum anti-Müllerian hormone (AMH) has emerged in the clinical literature as a marker of ovarian reserve. AMH is produced by healthy growing follicles and thus it serves as both a marker of follicle health as well as an indirect marker of follicle reserve (Verma et al., 2016). To wit, circulating AMH concentrations are lower in women who smoke relative to a control population (Plante et al., 2010),

suggesting that it may be a useful biomarker of effect. However, AMH has not been validated for use as a clinical marker of effect as it is unclear how it is influenced by body mass index, comorbidities, physical activity, and diet.

Clinical markers are also lacking for common gynecological disorders such as PCOS and endometriosis. Accordingly, novel biomarkers of effect and diagnostic markers of reproductive disease continue to be an unmet need. Recent studies employing phenomics, genomics, proteomics, and metabolomics are being brought to bear on the issue. Increasingly there is recognition that single markers may not have adequate sensitivity and specificity to be predictive of disease and thus marker panels have also been explored. Of the techniques emerging, research into the exosome and measurement of the concentrations of small non-coding RNA such as microRNA (miRNA) and piwi-interacting RNA (piRNA) have shown promise as potential clinical markers; however, issues of validity, reproducibility, and predictive value remain to be addressed. Hence, experimental animal studies continue to be necessary for identification of potential chemical hazards.

Experimental Evidence and Biological Plausibility

Owing to the potential for serious adverse health effects with potential life-long health consequences following exposure to chemicals, screening tests have been developed to identify potential health hazards. Animal studies are highly valuable in this arena because they allow for the testing of adverse effects using defined concentrations of test chemicals of known purity in genetically similar animals, under stringent conditions and distinct developmental stages in the absence of confounding comorbidities – all conditions that cannot be achieved in human studies.

Regulatory test methods– Regulatory test guidelines have been established by various federal and international agencies in an effort to standardize testing methods across laboratories following the same guideline. Although each test guideline developed by different regulatory bodies differs from its counterpart designed by other regulatory bodies, their aim remains the same. Specifically, these regulatory studies are designed to evaluate test chemical effects on a broad range of endpoints that cover all major reproductive and developmental events in a single screening assay that can be routinely carried out in standard laboratories. Broadly, reproduction can be broken down into six stages, which are typically assessed using a combination of three *in vivo* studies. Stage 1 encompasses pre mating to conception, Stage 2 comprises conception to implantation, Stage 3 covers implantation to the closure of the hard palate (considered the end of major organogenesis), Stage 4 includes the time between the end of major organogenesis to parturition, Stage 5 embodies birth to weaning and Stage 6 comprises weaning to sexual maturity (Parker, 2012). The main regulatory studies designed to assess adverse effects of potential toxicants on the reproductive system across all stages of reproduction are: the fertility and reproductive toxicity study (which allows for the assessment of effects on stages 1 and 2), the prenatal and developmental toxicity study (which covers stages 3 and 4), and the prenatal and postnatal study (which combines stages 3 through 6). For a listing of regulatory test guidelines put out by the various agencies, the reader is directed to Hoberman and Lewis (2012). Reproductive performance measures the steps in the reproductive cycle beginning with mating and includes gestation length that captures the processes of fertilization, implantation, embryogenesis, and fetal development followed by birth, lactation, puberty, and gametogenesis. Key outcome measures assessed are the mean time to mating (precoital interval), litter size, sex ratio, and mating, fertility, gestation, live birth, and survival indices. Developmental landmarks include birth weight, anogenital distance (AGD), eye opening, pinna unfolding, vaginal opening, and soft tissue and skeletal anomalies (e.g. vaginal septum).

All *in vivo* test guidelines, irrespective of their aim, require the measurement of tissue weights for all major organs and histopathological assessment. Test guideline-specific outcome measures include: vaginal cytology; uterine and ovarian histology (including assessment of ovarian follicle counts); circulating serum hormone concentrations (luteinizing hormone (LH), FSH, prolactin (PRL), estradiol (E₂) and progesterone (P₄). In recent years, hormones such as inhibin, activin, and AMH have been added to the list of target hormones; however, although useful for research purposes they have not been validated as biomarkers of adverse effect in a regulatory context.

These regulatory studies are designed to produce robust reproducible data for regulatory risk assessment purposes. Owing to the large volume of data produced and the potential for type I error, it is essential to evaluate each outcome against concurrent controls; however, in the event that control data falls below the normal range for the outcome of interest it may be necessary to consider using historical control data. If comparing with historical controls it is best to use contemporary controls from the same laboratory though this may not always be possible and thus historical controls from the literature may also be employed. In addition, it is important to integrate the data and ensure biological consistency across multiple related outcome measure to ensure that data are statistically significant, biologically relevant, and compound related. Results from regulatory studies help define the no or lowest observable adverse effect level (NOAEL or LOAEL) for the most sensitive adverse outcome measure. Data generated from such studies are useful in identifying potential hazards that, together with human exposure data, contribute to the risk assessment process (Council NR, 1983).

Regulatory studies have proven to be valuable for the identification of reproductive and developmental hazards and possess a number of strengths including: multiple dose groups; robust sample size typically providing adequate statistical power; genetically similar animals that have been shown to be sensitive to reproductive toxicants; an appropriate route of exposure; and integration of multiple physiological processes over specific stages of an organism's lifespan directly related to the stage of reproduction or development being evaluated. These studies are conducted according to internationally harmonized test guidelines in accordance with good laboratory practices (GLP) and standard operating procedures (SOPs), which together

enhance study reliability and generate reproducible data. Although GLP and the use of SOPs enhances study reliability and reproducibility of data, they cannot provide mechanistic insight and cannot provide an assessment of all potential pathophysiological processes that may reveal more sensitive reproductive/developmental outcomes. While regulatory screening methods provide an integrated assessment of reproductive and developmental function, there are a number of inherent weaknesses as well. The fundamental assumption in developmental and reproductive toxicology is the ability of the models employed to predict human response. However, while basic events in development are highly conserved across species, the pharmacokinetics of the maternal metabolism varies greatly resulting both false positives and negatives depending on whether the parent compound or its metabolite causes toxicity. Moreover, these screening assays are time consuming and expensive to carry out. The statistical power necessary to make confident conclusions from the data necessitates large numbers of animals and requires a large testing capacity for the laboratories undertaking these studies as they take several months to conduct due to the length of gestation and the time required following tissue collection to process and evaluate the data obtained. Additionally, most regulatory tests are conducted solely in one strain of a species, which can affect the endpoints displaying adverse effects. Use of the most sensitive strain is recommended, but it is not always immediately apparent which strain fits that condition. Inter-lab variation of data interpretation can alter the assessment of toxicity of a chemical, particularly with respect to examination of fetal morphology. Specifically, evaluation criteria and nomenclature have evolved substantially over time, making the standardization of these criteria difficult particularly in light of the fact that individual laboratories utilize different strains, assess fetuses on different days of gestation and possess large volumes of historical data based on their own criteria (Carney et al., 2012). Moreover, test guidelines often require evidence of a dose-response when assigning importance to an effect; however, in the event where one does not exist, particularly where fetal malformations are concerned, it is incumbent upon the testing laboratory to look at whether or not the reason for a lack of dose-response is due to fetal death, whereby the most affected conceptuses at the highest dose died and thus weren't available for assessment at parturition. Physiological and anatomical differences in the type of placenta utilized by test species and humans create discordance between results in a test species and the plausibility of it occurring in humans. Maternal toxicity can further muddy the waters with respect to interpretation of the data generated in reproductive and developmental toxicity studies, as developmental toxicity often occurs at the same dose at which maternal toxicity occurs, making causal determination difficult. Lastly, no routine test guidelines directly test for changes in mating behavior though it is susceptible to disruption by toxic substances (Ben Slima et al., 2017) and represents a significant concern for human reproduction.

Traditional tests employ a control group plus three dose levels designed to produce a graded response and which encompass a NOAEL, a mid-dose which elicits minimal observable adverse effects and a high dose designed to elicit clinical signs of toxicity (maternal and/or developmental) but not death or suffering. However, the high dose exposure, which is not representative of human exposure of the vast majority of chemicals, can overwhelm the detoxification machinery, leading to shifts in the metabolism of the test compound and altered toxicokinetics. Changes in toxicokinetics may produce false positives, leading risk assessors to erroneously classify compounds as harmful when in fact they are not. Important differences in biochemistry, exposure, and metabolism leave uncertainty and thus experimental animal studies designed to elucidate key mechanisms underlying observed toxic phenomenon are frequently pursued in hypothesis-driven experimental studies. Furthermore, these screening tests are not designed to provide information on target tissue exposure or MOA but may suggest a mode of action.

High throughput screening methods—To address some of these shortcomings, Tox21, a tiered testing paradigm for the 21st century (Thomas et al., 2013), was proposed to provide high throughput solutions to regulatory agencies facing the challenge of assessing the thousands of chemicals currently used in commerce but which are lacking conventional toxicity data by increasing the speed, efficiency and accuracy of toxicity testing. It represents a shift from traditional *in vivo* animal tests to *in silico* modeling, high throughput screening (HTS) of human cells *in vitro*, and toxicogenomics. This tiered testing paradigm is divided into three tiers, designed to address the question of a chemical's toxicity, as well as to elucidate potential MOA, while reducing the numbers of animals required to do so at the same time allowing for limited testing in animals as required to fill data gaps not answered by the early tiers. The testing protocol is still in its early inception and thus requires the generation of a robust database of integrated studies demonstrating the comparable application of these methods with the traditional tests, which are the current gold standard used for risk assessment purposes. Its utility and reliability in predicting MOA using only *in silico* and *in vitro* methods continues to be improved upon; however, in the absence of conventional toxicity tests, these modeling methods can be useful in providing toxicity data for risk assessment.

Mechanistic studies—In reproductive toxicology it is difficult to completely replace animal studies with tissue culture screens owing to issues related to critical windows of exposure (Pryor et al., 2000) and complex interaction of multiple specialized cell types whose physiology remains imperfectly understood. However, advances have been made in several areas that provide insight for screening chemicals and exploring potentially important mechanistic pathways. Mechanistic studies enhance the data generated on a given test chemical by identifying potential effects on pathophysiological processes as well as gene, protein, lipid, and miRNA expression. This in turn provides insight into central mechanistic pathways that could be incorporated into cell-based screening assays or identify more sensitive outcomes to drive regulatory decisions to protect human health. Regulatory studies are already complicated, time consuming and expensive and thus the risk of further complicating these studies must also be considered. Mechanisms of toxic action are explored in specialized culture systems such as granulosa and isolated ovarian follicle culture studies.

Granulosa cell cultures exploit the availability of mural granulosa cells obtained following oocyte retrieval in ovulation induction cycles. While there are obvious benefits of using human primary cells from the developing follicle, these cells are terminally

differentiated and obtained from women who have compromised fertility and thus may not be representative of granulosa cells from healthy fertile women. To obviate these limitations, some investigators have employed rodent antral follicle cultures to assess the effects of target chemicals on follicle growth, ovarian steroidogenesis, and target protein expression (Basavarajappa et al., 2011; Peretz et al., 2010; Peretz et al., 2012). However, these cells are obtained following gonadotrophin stimulation to maximize the number of cells obtained and are limited to the assessment of compound effects on a narrow follicle development stage and in an artificial environment. In an attempt to mitigate these issues and to better understand the impact of test chemicals on the development of follicles, isolated ovarian follicle culture systems have been developed to evaluate the time- and stage-dependent effects of test chemicals on follicle development, ovulation, and fertilization (Cortvrindt et al., 1998). Two-dimensional pre-antral follicle cultures have been used to demonstrate follicle stage- and time-dependent effects of ovarian toxicants (Neal et al., 2007; Sadeu and Foster 2011a, 2011b). Isolated follicle culture methods have been further enhanced to allow for three-dimensional growth to better approximate in vivo conditions (Jin et al., 2010; Kreeger et al., 2005; Xiao et al., 2017b). Recent developments have extended culture techniques to include the reproductive tract on a chip that will enable assessment of test chemical effects on the menstrual cycle in culture (Xiao et al., 2017a).

Challenges and Future Directions

There are many challenges facing reproductive biologists and toxicologists hoping to protect the health of women over the course of their lifetime. While the pressing need for novel clinical markers of disease are well recognized and their potential application in toxicology is appreciated, it is unclear if the search for individual markers or panels of markers will be more productive. Advances in omics biology have been very exciting revealing mechanisms underlying dysregulation of signaling pathways in gynecological diseases. Markers identified in these studies have potential as outcome measures to detect sensitive effects of test compounds. Moreover, the validity of the biomarkers must be demonstrated and their relationship with an adverse health outcome demonstrated. Another challenge will be how to integrate new outcome measures into the risk assessment review process. Moreover, it must be appreciated that there is a profound difference between screening assays for hazard identification and studying mechanisms of action. Results of mechanistic studies are indeed valuable; however, their role and contribution to the risk assessment process requires evaluation. Adverse outcomes must be valid and linked with a potential adverse outcome in women.

Glossary

Blastocyst An early embryonic structure forming a hollow ball of cells which have begun the process of differentiation.

Corpus luteum A hormone-secreting structure that develops in an ovary after ovulation occurs.

Developmental exposure An exposure occurring during the period of fetal development; also known as gestational and in utero exposure.

Embryogenesis The process by which the embryo forms and develops.

Endometriosis A disorder in which tissue that normally lines the uterus grows outside the uterus.

Epidemiological studies Studies that analyze the patterns, causes, and effects of health and disease conditions in defined populations.

Epigenetic regulation A process during which gene expression is controlled through changes in a chromosome without alterations in the DNA sequence.

Estrogenicity The ability of an agent to mimic the effects of estrogen in a cell or tissue.

Estrous cyclicity Process through which the recurring physiologic changes that are induced by reproductive hormones in a female are monitored via vaginal washings.

Follicular atresia The process through which ovarian follicles are lost.

Folliculogenesis The maturation of the ovarian follicle; describes the progression of small primordial follicles into large preovulatory follicles.

Germinal vesicle breakdown Refers to the dissolution of the nucleus of an oocyte that is arrested in prophase of meiosis I in response to hormonal stimulation prior to ovulation.

Gestational age The term used to describe how far along a pregnancy is.

Gestational exposure An exposure occurring during the period of gestation or pregnancy; also known as developmental and in utero exposure.

Gonadal differentiation The process during which an undifferentiated gonad develops into a male or female gonad.

Implantation The stage of pregnancy at which a fertilized egg adheres to the wall of the uterus.

Imprinted gene A gene that is expressed in a parent-of-origin-specific manner.

In vitro fertilization The process of fertilization by manually combining an egg and sperm outside of the body.

Leiomyoma Noncancerous growths in the uterus; also known as fibroids.

Meiotic resumption Process during which a developing oocyte exits the arrested stage and completes meiosis I in preparation for ovulation.

Micro RNAs A small non-coding RNA molecule that functions in RNA silencing and post-transcriptional regulation of gene expression.

Myometrial Related to the middle layer of the uterine wall consisting of uterine smooth muscle cells, and supporting stromal and vascular tissue.

Oocyte-cumulus complexes An oocyte surrounded by specialized granulosa cells released during an ovulation.

Oocyte maturation Process during which oocytes re-entry meiosis just prior to ovulation.

Oocyte retrieval Technique used in in vitro fertilization to remove oocytes from the ovary to achieve fertilization outside the body.

Oogenesis The differentiation of the oocyte into an ovum capable of fertilization and further development into an individual.

Oxidative stress An imbalance between the production of free radicals and the ability to counteract their harmful effects through neutralization by antioxidant.

Preterm birth A birth that occurs before the 37th week of pregnancy.

Primordial follicle recruitment Step of folliculogenesis during which a dormant primordial follicle is activated and begins development towards the primary follicle stage.

Steroidogenesis The process by which steroids are generated from cholesterol.

Trophoblast Is the layer of tissue located on the outside of an embryo that supplies it with nourishment and later forms the placenta.

Zygotes A diploid cell resulting from the fusion of two haploid gametes; a fertilized egg.

Introduction

In the first part of her book on humanity's love story with plastics, Susan Freinkel describes the history of plastics and how they have changed our lives (Freinkel, 2011). Plastics have changed our lives by eliminating the limitations of requiring only natural products to satisfy our everyday needs. Their versatility gave us the ability to create many new products in a cost-effective manner which also translated into better opportunities for those of modest means to acquire previously unattainable products. The name "plastic" comes from a Greek verb that means "to mold of shape" and truly describes this wonderful invention. From the invention of celluloid to more complex contemporary plastics, humans have been in contact with these products for nearly 150 years. Ironically, a key chemical feature of the most versatile plastics allows the compounds forming their backbone to escape the products they are in and enter the environment and, hence, wildlife and humans.

This chapter introduces the reader to current knowledge about plastic compounds and their interactions with the female reproductive system. An emphasis on two widely known plasticizers, bisphenol A and phthalates, is taken to summarize both classical and contemporary studies highlighting the effects of these chemicals. Major reviews of the literature are cited and included as suggested readings in hopes of stimulating the reader to examine these thorough reports in their quest to learn more about these compounds.

Bisphenol A (BPA) is a plasticizer used in a variety of consumer products including polycarbonate plastics, the epoxy resins that line aluminum cans, and thermal receipts. Due to its ability to leach out of products, BPA has been detected in many human tissues including urine, serum, breastmilk, and ovarian follicular fluid. In their thorough review of experimental and human studies published between 2007 and 2013, Peretz et al. (2014) concluded that BPA is a reproductive toxicant based on its ability to disrupt ovarian, uterine, and developmental function. Furthermore, a detailed review of studies published between 2007 and 2016 by Ziv-Gal and Flaws (2016) has summarized current evidence for BPA-induced infertility.

Phthalates are synthetic chemicals used in polyvinyl chloride plastics, beauty and infant products, medical devices and on the enteric coating of some medications. As with BPA, phthalates are not covalently bound to the products in which they are used, thus, they are able to leach out into the environment under a variety of conditions. One challenging aspect of understanding phthalates as endocrine disruptors is that, contrary to BPA, they are a chemical class that includes many related chemicals. The basic structure of a phthalate includes a phthalic acid and alkyl chains of various lengths and functional groups. This diversity of chemical structures allows phthalates to potentially interact with a large variety of tissues. Like BPA, the epidemiological and experimental animal literature examining the relationship between phthalate exposure and adverse female reproductive health outcomes has been systematically reviewed previously by Kay et al. (2013). In their report, Kay et al. (2013) conclude that despite a paucity of data in specific research areas for several phthalates, there is sufficient evidence supporting phthalates as reproductive toxicants. Based on classical studies assessing phthalate toxicity, it was thought that phthalates could only cause reproductive toxicity at high concentrations. Interestingly, newer reports employing environmentally relevant doses of phthalates (i.e. those that resemble human exposures) and evaluating their effects on reproductive processes have highlighted aspects of phthalate toxicity that were not as obvious in high dose classical studies.

In the following sections, the status of our knowledge regarding BPA and phthalates will be summarized with an emphasis on their effects on various aspects of ovarian and uterine function (Fig. 1) as well as developmental processes including embryogenesis, placental, and pregnancy (Fig. 2). In the case of phthalates, most studies have focused on di-2-ethylhexyl phthalate (DEHP), di-n-butyl phthalate (DBP), and butyl benzyl phthalate (BBP) as well as their primary metabolites mono-2-ethylhexyl phthalate (MEHP) and mono-butyl phthalate (MBP; common metabolite for DBP and BBP), respectively. Very few studies have characterized the reproductive toxicity of other phthalates, thus, most of this section will be concerned with DEHP, DBP, and BBP and their metabolites.

Effects of Plastic Compounds on Ovarian Function

The ovary is responsible for oogenesis, folliculogenesis, steroidogenesis and ovulation in the female. Therefore, proper ovarian development and function are absolutely required for female fertility. Naturally, any chemical exposure that causes disruptions in these processes has the potential to cause infertility. The processes of ovarian follicle formation, oocyte meiosis, and steroidogenesis are particularly sensitive to environmental stressors. Ovarian toxicants are agents that cause detrimental effects on the ovary. Due to the diversity of processes that control ovarian development and function, ovarian toxicants can cause adverse effects via a variety of mechanisms. BPA and phthalates have been shown to intervene with processes required for the proper development of the ovary in the womb, the assembly and maturation of ovarian follicles, ovarian hormone production, and the ability of oocytes to mature into fertilizable eggs.

Oogenesis and Folliculogenesis

The processes of oogenesis and folliculogenesis ensure that the female will have a complement of fertilizable eggs to give rise to healthy offspring. Disruptions in these processes increase a female's risk for adverse reproductive outcomes including premature menopause, infertility, and early pregnancy loss to name a few. Many studies have assessed the impact of plasticizer exposures on these processes and found the effects of BPA and phthalates to be detrimental to them. Exposure to BPA in the womb, has been reported to cause defects in the process of oogenesis in mice and macaques. Specifically, developmental exposure to BPA affects the onset of meiosis, the accuracy with which chromosomes pair and recombine during meiosis, and disrupts the expression of key meiosis and mitosis genes in early oocytes and their precursors. Human fetal oocytes exposed in vitro to BPA undergo increased degeneration, have

Fig. 1 Aspects of ovarian and uterine function susceptible to plastic exposure. According to human and animal studies various aspects of ovarian and uterine function may be targeted by plastic exposures. Overall, these processes include ovarian oogenesis, folliculogenesis, steroidogenesis, and susceptibility to oxidative stress and PCOS. In the uterus, processes involved include uterine morphology, endometrial function, hormone signaling, uterine function, and oxidative stress.

increased chromosome recombination defects, and show altered gene expression patterns when compared to control treated oocytes. Also, mouse oocytes exposed to BPA *in vitro* show increased errors in the epigenetic regulation of maternally imprinted genes. Following gestational exposure, BPA increased the incidence of multi-oocyte follicles in lambs and macaques. In mice and macaques, various studies suggest that gestational exposure to BPA causes an increase in unenclosed oocytes (not encased within follicles), decreased number of primordial follicles and increased follicular atresia. Several studies in lambs and rats have also provided evidence that BPA alters the rate at which follicles transition through their various stages of development during folliculogenesis. A study in sheep exposed prenatally to BPA revealed that BPA exposure disrupts gonadal differentiation and folliculogenesis by altering the expression of microRNAs required for the regulation of these processes. Interestingly, there seem to be dose-specific effects of BPA exposure. Specifically, low doses of BPA have been shown to accelerate the growth of preantral follicles *in vitro*, while higher doses have been shown to alter cell cycle and apoptosis gene expression and cause atresia in cultured mouse antral follicles.

Phthalates have been shown to cause various disruptions in follicular and oocyte development. Interestingly, phthalates have been shown to disrupt folliculogenesis at various levels of follicle maturation as well as at various ages or developmental stages in rodents. Phthalate exposures have been shown to cause imbalances in the number of unenclosed oocytes, the rate of primordial follicle recruitment, numbers of primary, secondary, and antral follicle numbers. Results indicate that disruptions in phosphatidylinositol 3 kinase (PI3K) signaling pathway, cell cycle/apoptosis dysregulation, and increased oxidative stress are likely mechanisms for phthalate-induced alterations in folliculogenesis. *In vitro* studies have also provided evidence for phthalate effects on follicle survival and function. Specifically, ovarian follicles treated *in vitro* with phthalates show significant growth inhibition, reduced estrogen production, and increased apoptosis. In pregnant mice, phthalates have also been shown to inhibit the function of the post-ovulatory gland known as the corpus luteum.

Steroidogenesis

Ovarian steroidogenesis is the process through which ovarian cells produce hormones for the maintenance of reproductive tissues, regulation of ovarian function and ovulation, and establishment of pregnancy. BPA and phthalate exposures have been associated with disruptions in ovarian steroidogenesis in various human and animal studies. Studies on women undergoing *in vitro*

Fig. 2 Aspects of embryo development, placental function, and pregnancy susceptible to plastic exposure. According to human and animal studies various aspects of embryo development, placental function, and pregnancy may be targeted by plastic exposures. In the embryo, overall quality, viability, nutrition, progression through the appropriate stages of development, the ability to implant in the uterus may be disrupted by plastics. In placental cells, plastics seem to affect proliferation, apoptosis, epigenetic regulation, gene expression, and hormone producing potential. Overall in pregnancy, plastic exposures are suspected to increase pro-labor gene expression, induce preterm birth, pregnancy losses, and, in some cases, increase gestational age at birth.

fertilization have provided evidence for associations between BPA exposure and impaired hormone levels. Specifically, the level of BPA exposure in women has been associated with a decrease in peak serum hormone levels (prior to oocyte retrieval), increased testosterone and androstenedione levels, and disrupted expression of the hormone-producing enzyme, aromatase. Studies in laboratory animals have provided evidence for effects of BPA on hormone levels although the direction of these changes has been equivocal. For example, some studies in rodents reported that BPA exposures lead to increased levels of estrogen, its hormone precursors and their receptors, while other studies found no effects on levels of these hormones as well as the enzymes that produce them and the receptors that detect them. Furthermore, *in vitro* studies have demonstrated that the effects of BPA exposure on ovarian steroidogenesis are dependent on the BPA concentration used and the type of ovarian tissue exposed. Overall, production of estrogen and its precursors is mostly thought of as being sensitive to BPA exposure. Finally, there is suspicion that BPA exposure could be associated with polycystic ovary syndrome (PCOS) and/or a PCOS-related phenotype. This is based on studies reporting associations between BPA exposure level and PCOS hallmarks such as increased serum androgen levels and insulin resistance in PCOS patients. Furthermore, rodents experimentally exposed to BPA show a phenotype reminiscent of the hallmarks of PCOS including disruption of estrous cyclicity and accumulation of ovarian cysts and large ovarian antral follicles.

Like BPA, phthalates have been shown to disrupt the process of steroidogenesis in the ovary. Both DEHP and its metabolite MEHP have been shown cause disruptions in ovarian steroidogenesis by decreasing estrogen synthesis through alterations in the expression of enzymes required for its synthesis and inactivation in ovarian tissues and/or cells derived from humans, mice, and rats. Furthermore, in cultured follicles from mice and oocyte-cumulus-complexes from pig, phthalates were shown to cause a precocious increase in the synthesis of the estrogen precursor, progesterone. Finally, a study in mice demonstrated that phthalate exposure increases steroidogenesis inhibiting secretions from the anterior pituitary and causes a decrease in serum progesterone levels, thus, suggesting the involvement of the anterior pituitary in phthalate-induced disruptions in ovarian steroidogenesis.

Oocyte Maturation

Although fewer in number relative to folliculogenesis and steroidogenesis, studies characterizing the effects of BPA exposure on oocyte yield, maturation, and fertilization have provided enough evidence to suspect that BPA exposure could adversely affect

oocyte maturation and function in women. Epidemiological studies in women undergoing in vitro fertilization have demonstrated associations between increased BPA exposure and decreased oocyte quality, decreased oocyte retrieval, and decreased maturation and fertilization in retrieved oocytes. In animal models, the effects of BPA exposure on germinal vesicle breakdown and polar body extrusion are not completely understood since various studies have shown contradicting results or no detrimental effects. In vitro exposures to BPA have been shown to cause defects in spindle formation, congressional failure, chromosome misalignment, and meiotic arrest in mouse and human oocytes. Collectively, phthalates have been shown to disrupt oocyte function by decreasing their viability, causing alterations in heritable DNA methylation patterns, increasing the number of degenerating oocytes and follicles in the fetal rat ovary, and causing dysregulation of pro-steroidogenesis lipid and cholesterol synthesis in cultured human fetal ovaries. Furthermore, phthalates have been reported to cause disruptions in oocyte maturation including the oocyte's progression through the stages of germinal vesicle breakdown, meiotic resumption, and meiotic spindle formation in various species including zebrafish, cows, mares, mice and rats. Additionally, phthalate exposures have been shown to result in oocyte and accompanying cumulus cell apoptosis, increased oxidative stress, inhibited cumulus cell expansion, poor quality embryos, and defects in ovulation and corpus luteum formation and function in various species including livestock, zebrafish, rats, and marmosets.

Effects of Plastic Compounds on Uterine Function

Appropriate uterine function is key to ensure that pregnancy is possible and to avoid reproductive diseases such as leiomyomas and endometriosis. Several studies have linked BPA and phthalate exposures to disruptions in uterine function. In the uterus, work in animal models has shown that BPA exposure leads to disruptions in the morphology of the uterus, function of the endometrium, and receptivity of the uterus for embryo implantation after fertilization. In women, epidemiological studies have reported that women with higher levels of markers of BPA exposure have increased odds of having endometriosis and implantation failure. Studies in prenatally and/or neonatally exposed mice have shown that BPA exposure leads to gross uterine lesions, decreased expression of key regulators of endometrial cell proliferation, and the formation of endometrial-like structures outside the uterus later in life. BPA has also been shown to interfere with apoptosis and hormone-stimulated uterine epithelium proliferation in neonatally exposed mice and with hormone receptor expression in the non-human primate uterus. BPA exposure during early pregnancy, has been shown to inhibit embryo implantation in mice and, through the paternal gamete, decrease implantation, pregnancy maintenance and increase early fetal loss. BPA-treated mice have also been shown to suffer proliferative lesions in their oviducts, which raises concerns regarding potential effects of this plasticizer on processes that depend on proper oviduct function such as fertilization and embryo transport. In vitro, BPA has been shown to decrease the proliferation of human endometrial stromal fibroblasts and endothelial cells, and to disrupt uterine cell contractions, oxytocin and prostaglandin signaling.

Phthalates have also been shown to be associated with uterine pathologies in women and to cause deviations in uterine function in rodents. In women, increased urinary concentration of markers of phthalate exposure have been associated with the presence and severity of endometriosis as well as with the occurrence of leiomyoma or fibroids. Phthalates have been reported to enhance the proliferative activity, exert anti-apoptotic effects, and increase collagen content in myometrial and leiomyoma cells derived from women. In adult rats, phthalate exposure was shown to alter hormone receptor levels in the uterus and to cause structural abnormalities such as decreased luminal diameter, thinning of endometrial layers, and disruption of the glandular epithelium. In pregnant mice, phthalate exposure was shown to compromise endometrial receptivity and impair embryo implantation by altering the expression of hormonal and signaling factors key to these processes. When multiple phthalates were administered together in a mixture with the goal of mimicking human exposure in mice, combined phthalate exposure was associated with increased uterine weight, an observation classically considered as a sign of estrogenicity. Finally, phthalate exposure has been shown to induce oxidative stress and inflammatory responses in primary endometrial cells.

Effects of Plastic Compounds on Embryo, Placenta and Pregnancy

Not much is known about the effects of BPA and phthalate exposures on embryo development and placental function, but the few studies current available support the idea that these plasticizers may impact these aspects of reproduction. As with many aspects of BPA research, this is an active area of study and further studies will likely provide enough data to elucidate the effects of BPA on pregnancy.

Embryonic Development

Defects in the processes of fertilization and early embryonic development can lead to pregnancy loss and developmental defects. In women, urinary concentrations of BPA have been associated with decreased rate of blastocyst formation and an increase in low-quality embryos during in vitro fertilization procedures. In studies using laboratory rodents, BPA exposure has been associated with delayed embryo development and disrupted expression of imprinted genes in embryos and placentas. A few studies have demonstrated the ability of phthalates to interfere with embryonic development. Specifically, phthalates have been shown to impair the formation of viable zygotes in rats, block the formation of two-cell embryos in mice, and cause altered gene expression in bovine blastocysts. In mice, phthalate exposure decreased embryo nutrition, an effect that was exacerbated in embryos with neural tube defects.

Placental Development and Function

Appropriate placental development is key to the survival, nourishment, and metabolic programming of the fetus. Defects in this process could lead to pregnancy loss and developmental and metabolic disease in adulthood. A small group of studies have evaluated the ability of BPA and phthalates to affect placental development and function. Specifically, in vitro studies have revealed that BPA exposure inhibits the rate at which placental cells proliferate and undergo apoptosis, an observation that could have significant implications for the proper development and nourishment of the fetus. These observations have been supported by studies in humans reporting that the placentas of women with greater urinary phthalate levels have altered miRNA, DNA methylation, and gene expression patterns. In placental cells, in vitro phthalate exposures have been shown to decrease aromatase activity, inhibit the process by which trophoblasts invade the endometrium during early placental development, disrupt regulation of placental cell apoptosis, and induce pro-labor gene expression. In mice, phthalate treatment reduced placental weight and area, disrupted vascularization, inhibited proliferation, and activated apoptosis of placental cells.

Pregnancy

In pregnant women, higher levels of BPA in urine have been associated with preterm birth. Interestingly, several studies have evaluated the ability of BPA to adversely affect pregnancy outcomes using animal models but have reported conflicting results. Specifically, some studies have reported defects in the number of pregnancies and pups delivered by BPA-treated animals while others reported observing no such effects. A potential association between phthalate exposure and pregnancy outcomes has been highlighted by studies showing that higher phthalate exposures are associated with increased risk for pregnancy loss and, in surviving pregnancies, with increased gestational age. Finally, phthalates have been shown to increase pregnancy loss and fetal mortality in rats.

Conclusion

In summary, plastics have given us the ability to mimic the usefulness of many natural products in an affordable way thanks to their versatility and low production cost. Ironically, the compounds that give plastics their desirable characteristics allow them to escape their products and enter our environment and bodies. A large body of work continues to accumulate and provide strong evidence for the ability of plastic compounds to interact with the female reproductive system and increase risk for adverse reproductive health outcomes. Although much work is still needed in specific areas and at concentrations that mimic human exposures, there is sufficient evidence to conclude that BPA and phthalates are significant concerns to female fertility. Finally, replacement of these chemicals in our products is currently the best way to manage the risks they impose to human and animal health. Although classical substitutes have fallen under intense scrutiny recently due to potential toxicity, a group of newer chemicals seem to have promising features such as cost effectiveness, low leaching potential, and low toxicity.

Metals in Female Reproduction

Sakhila K Banu, Jone A Stanley, and Joe A Arosh, Texas A&M University, College Station, TX, United States

Heavy metals have been used by humans since ancient times. Metals may be divided into four groups: (i) those with greatest toxicological significance that are wide-spread in the human environment, for example, arsenic (As), cadmium (Cd), lead (Pb), mercury (Hg), chromium (Cr), and uranium (U); (ii) essential trace metals, for example, copper (Cu), iron (Fe), manganese (Mn), selenium (Se), and zinc (Zn); (iii) other metals with evident biological or toxicological interest, for example, nickel (Ni) and vanadium (V); and (iv) metals of pharmacological interest, for example, aluminum (Al), gallium (Ga), and lithium (Li) (Banu, 2013). The focus of this article is twofold: (1) examination of the adverse or beneficial effects of commonly used metals, including essential trace metals on female reproductive function, and (2) consideration of the role of essential trace metals such as Cu, Fe, Mn, Se, and Zn on physiological aspects of female reproduction. Discussion related with each metal includes their beneficial and/or the adverse effects on humans. Additional information pertaining to other mammalian species, including primates and experimental animal models, source of exposure, maximum contamination limit (MCL) or minimal risk level (MRL), and half-life are given in **Table 1** for the metals included in this commentary.

Anthropologic use of heavy metals started long before the beginning of industrial revolution with earliest recorded use of heavy metals by humans dating to about 6000 BC (Adebowale, 2004). The *Stone Age* includes an extended prehistoric period that lasted for about 3.4 million years ending between 4500 BC and 2000 BC with the advent of metal usage. The subsequent ages of human history were named for introduction of the usage of metals. The *Copper Age* started around 6000 BC; the *Bronze Age* around 3200 BC, and the *Iron Age* began around 1200 BC. During the copper age, humans used an iron/nickel alloy that naturally occurred in iron/nickel meteorites. The production and usage of heavy metals increased exponentially after the industrial revolution (AD 1750–1850) (Banu, 2013).

Exposure to endocrine disrupting chemical (EDC), including heavy metals can cause adult reproductive failure, endocrine dysfunction, and nutrient homeostasis instability. Since the female mammals have their oocyte number determined by birth or soon after birth, the ovaries are direct targets for environmental insults. Any environmental insult to the ovary has the potential to affect the future generation of the affected individual. The placenta is the vascular interface between the mother and fetus, which helps regulate nutrient, oxygen, and waste exchange. It is evident that pregnancy related conditions, including intrauterine fetal growth restriction (IUGR) and preeclampsia, originate from placental dysfunctions. Placenta is a potential gateway for chemicals and toxicants to cross, resulting in adverse effects within the fetus and restricting fetal growth and development. Therefore, environmental influence on placental origin of adult diseases is a growing field to understand the influence of placenta in determining fetal health.

Arsenic

Arsenic (As) toxicity is a major global health concern due to its wide distribution and adverse health effects. The shallow ground water of the western United States is more contaminated with As than the eastern United States. Arsenic is used as a pesticide and to preserve wood from rot and decay. The oxidized form of As (arsenate) is the principal inorganic As species found in drinking water. Toxicity of arsenal compounds results in the production of free radicals that can cause DNA single-strand breakage. Exposure to As induces oxidative stress in several organs due to significant reduction in antioxidants. Exposure of pregnant women to As resulted in increased rates of abortion, preterm births, and neonatal mortality, as well as decreased birth weight, even at low exposure levels. Maternal exposure to As also decreased thymic size in the children and increased infectious diseases in both mothers and children, as a result of suppression of the immune system. Arsenic concentrations in pregnant women were negatively associated with birth weight, height and chest circumference (Liao et al., 2018). Fetal As concentration was negatively associated with head circumference. Maternal exposure to As during pregnancy increases oxidative stress and inflammation in the placenta by elevating proinflammatory cytokines (IL-1 β , TNF α , and IFN γ). Arsenic also silences gene transcription in umbilical artery and placenta.

Cadmium

Cadmium (Cd) is listed by the US Environmental Protection Agency (EPA) as one of the 126 priority pollutants. Soluble Cd salts accumulate in mammals and result in toxicity to various reproductive organs. Cd exposure is linked to numerous human health problems, including infertility. Cd accumulates in the ovary, uterus and pituitary of humans and alters the histopathology of these endocrine organs.

Cd is one of the EDCs with a long half-life of 20–30 years. An early study reported that Cd levels in the ovary increased linearly between 30 and 65 years of age. Below 30 years, there was no age dependent increase observed. However, over 65 years of age, ovarian Cd levels began to decrease. Interestingly, in smokers, the amount of Cd in the ovaries was elevated compared to

Table 1 Encyclopedia of metals

<i>Metal</i>	<i>MCL, MRL, SMCL, NL or PEL</i>	<i>Sources or uses</i>	<i>Species</i>	<i>Major finding/pathway(s)</i>
Aluminum (Al)	SMCL 0.05 to 0.2 mg/L	Leaching from rock and soil, mining, Al ores, coal-fired power plants and incinerators	Rats	Disrupted ovarian structure; altered metabolism of Fe, Zn and Cu; decreased activities of Na(+)-K(+)-ATPase, Mg(2+)-ATPase and Ca(2+)-ATPase in the ovary
			Mice	Placental atrophy, hemorrhagic uterus, intra uterine fetal growth restriction (IUGR) and increased embryo mortality
			Fish	Decreased protein deposition in eggs, decreased plasma levels of 17 α -hydroxyprogesterone
Arsenic (As)	MCL 0.01 mg/L	Natural erosion from land, discarded mine and mill tailings	Rats	Follicular atresia and thinning of uterine luminal diameter; decreased weight of the ovary and uterus; altered histomorphology of the uterus with degeneration of luminal epithelial cells and endometrial glands
			Mice	Spontaneous abortion with aberrant placental vasculogenesis and placental insufficiency
Boron (B)	NL 1000 μ g/L	Glass manufacturing, coal burning power plants, copper smelters, fertilizer, and pesticide	Rabbit	Increased fetal resorptions or fetal deaths, prenatal mortality; decreased litter size and number of live fetuses per litter; decreased gravid uterine weight, and vaginal bleeding associated with pregnancy loss in mothers
			Rats	Increased fetal resorption, IUGR, lethality of embryos and fetuses, decreased litter size, and fetal malformations
			Mice	Increased fetal resorption, decreased fetal weight, uterine weight, increased prenatal mortality and malformed fetuses
Cadmium (Cd)	MCL 0.005 mg/L	Corrosion of galvanized pipes, erosion of natural deposits; discharge from metal refineries; runoff from waste batteries and paints	Hamster	Ovarian lesions, diffused hemorrhage in all the developing follicles and interstitial cells
			Rats	Stromal hemorrhages and cellular degeneration in oviduct and uterus; ovarian follicular necrosis, persistent diestrus; increased weight and thickness of the uterine epithelium and endometrial stroma
			Mice	Hemorrhagic foci in the ovary and endometrial stroma
			Hen	Ovarian lesions with severe necrosis, and degeneration of ovarian follicles and apoptosis, and increased oxidative stress, decreased antioxidants and decreased steroidogenesis.
			Silk worm	Changes in the oviposition behavior, and reduced fertilization rates
Chromium (Cr)	MCL 0.1 mg/L (USEPA); 0.05 mg/L (WHO)	Industrial processes and manufacturing activities including discharges from steel and pulp mills, leather industries, paint pigments, automobile emissions, chrome plating, and corrosion inhibitors	Rats	Disrupted placental histology; increased cell death and oxidative stress, and decreased antioxidants in the placenta; caused premature ovarian failure, delayed puberty, extended estrus cycle, decreased pregnancy rate and disrupted ovarian steroidogenesis; advanced germ cell nest breakdown during fetal ovarian development, increased apoptosis of the oocytes and granulosa cells, and increased ovarian follicle atresia
			Mice	Decreased implantation and viable fetuses, decreased litter size, and increased fetal resorption; increased endometrial stromal cells apoptosis.
			Fish	Impaired vitellogenesis and decreased vitellogenic oocytes
Cobalt (Co)	MRL 0.03 μ g/m ³	Mining and mineral processing. Enters dust, seawater spray, volcanic eruptions, forest fires; and surface water or rainwater runoff	Rabbits	Decreased body weight
			Rats	Cobalt crosses the placenta, enters maternal blood, fetal blood and amniotic fluid and induced IUGR and fetal malformations.
			Mice	Decreased body weight, increased malformed fetuses, and induced postimplantation loss of the embryos
Copper (Cu)	MCL 1.3 mg/L	Mining, smelting and refining; Cu in wire, sheet metal, water pipes and fossil; and fuel combustion	Mice	Reduced number of healthy primordial, primary, growing, secondary and antral follicles and corpus luteum; induced ovarian lesions; and increased follicle atresia
			Crab	Lower gonadosomatic index

(Continued)

Table 1 Encyclopedia of metals—cont'd

<i>Metal</i>	<i>MCL, MRL, SMCL, NL or PEL</i>	<i>Sources or uses</i>	<i>Species</i>	<i>Major finding/pathway(s)</i>
Gold (Au)	No limit identified	Open pit mining, cyanide heap leaching, gold ore dumps. Gold treatment for rheumatoid arthritis	Human Rats	In utero exposures to gold resulted in stillborn birth, severe malformations of the newborn, decreased estriol levels, hypertension and proteinuria in mother Embryo toxicity at high doses; gold sodium thiomalate decreased fetal weight and caused fetal malformation, increased numbers of eosinophils and inflammation in endometrial and myometrial cells
Lead (Pb)	MCL 0.015 mg/L	Fossil fuels, industrial products, lead smelters, paints, pipes, cables, ceramics, stained glass and batteries	Monkey Rats Mice	Lead suppressed corpora luteal production of progesterone; suppressed the plasma levels of LH, FSH and E ₂ Delayed the timing of puberty, suppressed serum levels of insulin-like growth factor-1, luteinizing hormone, and estradiol; increased thickening of the endometrium, narrowing of uterine lumen, caused damage to endometrial glands and vacuolar degeneration. Decreased primordial follicles, increased atretic antral follicles; maternal exposure to Pb retarded embryonic growth, reduced litter size, induced IUGR and impaired postnatal survival. Progeny of the lead-exposed mothers experienced pubertal delay Decreased number of litters, increased number of fetal death; and decreased number of healthy primary follicles in the ovary.
Lithium (Li)	PEL 0.025 mg/m ³	Present in the earth's crust in 65 ppm; released from <i>mining</i> processes, and highly used to treat bipolar disorder	Rats	Teratogenic and fetotoxic; decreased cell proliferation in preimplantation embryos
Manganese (Mn)	SMCL 0.05 mg/L	Mn is an essential trace element. Found in air, soil, water, and food; disposal of Mn based products, fungicide, seed protectants, antiknock agent in gasoline, and a contrasting agent in nuclear magnetic resonance tomography	Rats Mice Fish	Altered myometrial cell proliferation; advanced puberty and elevated serum levels of LH, FSH, and estradiol Embryo toxicity with late resorptions, postimplantation loss and reduced fetal body weight Reduction in diameter and number of oocytes, formation of large inter follicular space, necrosis and vacuolation in the ovary with oocyte atresia, and decreased gonado-somatic-index
Mercury (Hg)	MCL 0.002 mg/L	Mining, burning coal and waste, natural deposits, industrial waste disposal and volcanic activity; skin lightening creams and dental amalgam, thermometers, fluorescent light bulbs, and blood pressure instruments	Hamster Rats Mice Fish	HgCl ₂ inhibited ovulation rate and increased the number of degenerated oocytes Prolonged estrus cycle, increased ovarian follicular atresia, increased irregular follicles with abnormal oocyte borders, and reduced number of ovarian follicles HgCl ₂ caused damage to the ovary and reduced the number of oocytes retrieved by superovulation; reduced oocyte quality and viability of oocytes, and reduced the rate of IVF Disrupted transcription of HPG-axis genes and impaired reproductive function
Molybdenum (Mo)	PEL 3 mg/m ³	Mining, smelting, coal-fired power plants and coal combustion	Cow Rats Mice	Cessation of milk synthesis. Prolonged estrus cycle, increased fetal resorption, decreased birth weight in pups, and had adverse effects on embryogenesis Ovarian hyperemia, increased oxidative stress, and altered ovarian function; poor oocyte quality and blastocyst quality, and degenerated blastocysts; impaired embryo development
Nickel (Ni)	MCL 0.1 mg/L	Oil and coal combustion, metal refining, sewage sludge and incineration	Rats Fish	Increased fetal mortality and fetal malformations, and IUGR Irregular shaped oocytes, scattered yolk granules in the inter follicular space, abnormal growth of the previtellogenic oocytes

Table 1 Encyclopedia of metals—cont'd

<i>Metal</i>	<i>MCL, MRL, SMCL, NL or PEL</i>	<i>Sources or uses</i>	<i>Species</i>	<i>Major finding/pathway(s)</i>
Platinum (Pt)	PEL 1.0 mg/m ³	Mining, catalytic converters, laboratory equipment, electrical contacts and electrodes, thermometers, dentistry equipment, and jewelry. Pt-containing compounds used for cancer chemotherapy	Rats	Interstitial edema and dilation of blood vessels of the ovary, inflammation of follicular epithelium, theca cells and corpus luteum; primordial follicle degeneration and oocyte degradation
Selenium (Se)	MCL 0.05 mg/L	Weathering of rocks and soils, Se in air from burning coal or oil	Duck	Decrease in the rate of egg hatching; yolk peritonitis in egg, malformed embryo and infertile egg
			Hen	Decreased egg weight and hatchability rate at very high doses 7 and 9 ppm
Strontium (Sr)	MCLG 4.4 mg/L	Ceramic manufacturing and glass products, pyrotechnics, paint pigments, fluorescent lights manufacturing	Human	Increased perinatal mortality rates in the regions of Ukraine and Belarus surrounding the Chernobyl site correlate with the strontium content in pregnant women
			Mice	Reduced oocytes in the fetal ovary, and reduced reproductive capacity.
			Rats	Reduced implantation, increased fetal resorption and embryo mortality, induced developmental defects, and IUGR
Thallium (Tl)	MCL 0.002 mg/L	Coal burning power plants, cement factories, and smelting operations	Human	Prematurity and IUGR
			Rats	Reduced ovarian cell viability and decreased glutathione (GSH), and GSH peroxidase and GSH reductase activities; embryo toxicity and increased fetal death; decreased number of live fetuses
Tin (Sn)	PEL 0.1 mg/m ³	Mining, coal and oil combustion	Rats	Pregnancy failure, preimplantation loss, postimplantation loss, fetal resorptions, and fetal death; embryo toxic and teratogenic, and atrophy of uterine glands
Titanium (Ti)	PEL 15 mg/m ³	Emissions from facilities, chemical and industrial processes such as petrochemicals, pulp and paper	Mice	Increased Graafian follicles and corpus luteum; increase in atretic follicles, intense inflammatory response and ovarian necrosis; reduced number of mating and pregnancy rate; smaller uteri and smaller fetuses, reduced serum concentrations of P ₄ , LH, FSH, and testosterone
Uranium (U)	MCL 30 µg/L.	Wind and water erosion and volcanic eruptions, mining, milling, and processing of uranium	Rats	In utero exposure to uranium decreased pregnancy rate, affected labor, and decreased survival rate of offspring
			Mice	Reduced pregnancy rate; decreased number of litters, decreased weight and diameter of placentas, decreased number of embryos, caused irregular estrus cycle, increased percentage of dysmorphic oocytes; and altered ratio of primary to secondary follicles
			Fish	Decreased number of spawning and the number of eggs per spawn; increased mortality of F1 embryos; decreased circulating concentrations of vitellogenin
Zinc	SMCL 5 mg/L	Mining, purifying of Zn, Pb, and Cd ores, steel production, coal burning, and burning of wastes. Disposal of Zn wastes from metal manufacturing industries and coal ash from electric utilities	Sheep	Induced severe copper deficiency and caused a high incidence of abortions and stillbirths
			Rats	A two-generation study with ZnCl ₂ exposure reduced fertility, viability and litter size, as well as uterus weight in the offspring
			Mice	ZnCl ₂ significantly reduced fertility and litter size, and body weight.
			Fish	Decreased ovarian glycogen, cholesterol, total proteins and total lipid in the ovary

IUGR, intra uterine growth restriction; *IVF*, in vitro fertilization; *MCL*, maximum contaminant level; *MRL*, minimal risk level; *NL*, state notification level; *PEL*, personal exposure limit; *SMCL*, secondary maximum contaminant level.

nonsmokers. In multiparous women (> 3 children), a tendency to decreased Cd ovarian levels was observed. Thus, it was proposed that Cd might be a risk factor for conception and pregnancy in women in their forties. In the human subjects, different groups of individuals have been identified as being more susceptible to Cd exposure (e.g., individuals with a low iron status, mainly women). Therefore, it is important to identify vulnerable groups, especially when setting recommendations for daily intake of Cd. Exposure to Cd during human pregnancy through either occupational exposure or cigarette smoking has been linked to decreased birth

weights and premature birth, with the enhanced levels of placental Cd and decreased progesterone biosynthesis by the placental trophoblast. In the placenta, Cd decreases progesterone synthesis by decreasing cytochrome P450 cholesterol side-chain cleavage enzyme (P450_{scc}) which converts cholesterol to pregnenolone, the metabolic intermediate in the synthesis of most steroid hormones. In addition, Cd inhibits placental low-density lipoprotein receptor (LDL-R) mRNA resulting in decreased precursor of cholesterol from the maternal peripheral circulation. Cd affects steroidogenesis by interfering with the DNA binding zinc (Zn²⁺)-finger motif through the substitution of Cd²⁺ for Zn²⁺. Cd acts as an estrogenic compound by either mimicking or inhibiting the actions of endogenous estrogens. Cd alters human chorionic gonadotropin and zinc transfer in human placenta, and induced ultrastructural changes in the placenta such as syncytiotrophoblastic vesiculations, stromal edema, vacuoles in Hofbauer cells and necrosis.

There is a sexual dimorphism in Cd accumulation, where women have higher internal levels of Cd than men, due to higher gastrointestinal absorption of Cd in women with low iron stores or due to genetic factors. Further, pregnant women appear to accumulate more Cd than nonpregnant women. A recent study in pregnant women from China on qualitative placental proteomic analyses demonstrated that prenatal Cd exposure at an electronic waste disposal area caused significant changes in proteins of mitochondrial respiratory chain (Xu et al., 2016). Cd exposure in pregnancy alters fetal DNA methylation in a marked sex-specific manner. Besides various molecular mechanisms such as genetic and epigenetic changes, increased oxidative stress and lipid peroxidation play key roles in Cd-induced female reproductive toxicity. Cd exposure during pregnancy leads to accumulation in the placenta, disturbed zinc transfer to the fetus, interferes with glucocorticoid balance, and affects the regulation of insulin growth factor-related proteins. It has been shown to inhibit the migration of human placental trophoblast cells. Finally, prenatal exposure to Cd causes changes in the epigenetic machinery, which could possibly lead to adverse outcome of the fetal health.

Chromium

Hexavalent chromium (CrVI) usage is increasing exponentially worldwide; and Cr pollution is a continuous, ongoing global problem. A report from the Environmental Working Group indicates increasing CrVI levels in 35 cities in the United States (Banu, 2013). At least 74 million people in nearly 7000 communities drink tap water polluted with total Cr. Unlike most other divalent metal ions, CrVI is unique, specific, and behaves like an anion due to its structural similarity with anions (such as CrO₄²⁻, HCrO₄⁻, and SO₄²⁻). Due to its anionic nature, CrVI is rapidly transported into cells through anion transporters and reduced to CrIII by various antioxidants such as ascorbate (vitamin C), GSH, cysteine and antioxidant enzymes (Banu, 2013).

Cr disrupts ovarian function in women working in Cr industries who exhibited increased levels of Cr in their blood and urine. Exposed women experienced abnormal menses, infertility or increased postpartum bleeding. Several reports from studies on experimental animals demonstrate adverse effects of CrVI on the ovary. Brief details are described in Table 1. Premature ovarian failure (POF) is a defect of ovarian follicle development and is characterized by primary or secondary amenorrhea, with elevated levels of gonadotropin hormones or by early menopause. *Xpnep2* is a marker gene in POF women, which is located on the X chromosome. Findings from our laboratory using rat as an experimental model indicate that prenatal exposure to CrVI disrupts *Xpnep2* gene during ovarian development, resulting in POF (Banu et al., 2015). However, it is not known whether there is a correlation between CrVI exposures in women and POF. Preterm birth is a leading cause of infant mortality and significant precursor to future morbidity.

Premature abortion and preterm birth are common problems in Cr-exposed women. Every year, about 15 million babies are born prematurely, and more than one in 10 of all babies born around the world are premature. Cr can transfer through the placenta to developing fetuses. A recent birth cohort study evaluated the association between maternal CrVI exposure during pregnancy and the risk of preterm birth among 7290 pregnant women in Hubei province, China. Data indicated an increased risk of preterm birth associated with higher maternal urinary Cr levels, and the associations appeared to be more evident in male infants. Thus, Cr not only causes preterm birth, it is also sexually dimorphic. Recent epidemiological and clinical data indicate that environmental CrVI exposure in women living in Willits, California adversely affects pregnancy outcomes and subsequent health of two generations, resulting in low birth rate, higher risk of pregnancy loss, and spontaneous abortion. Children (F1 offspring) of CrVI exposed women experienced respiratory problems, perinatal jaundice, and increased birth defects. The study was conducted using data released from the hospital records that included newborn records from 29,311-unexposed (control) and 5036-exposed (Willits population), as well as 31,444-unexposed (control) and 5558-exposed pregnant women (Willits population). For the first time, the detrimental reproductive effects of nonoccupational CrVI exposure in women and their infants in the United States was reported (Remy et al., 2017). Another epidemiological study indicated that occupational exposure to Cr during pregnancy caused intrauterine growth retardation (IUGR) and resulted in low birth weight of the newborn children. Increased levels of Cr in the blood and urine of chrome plating workers is associated with elevated levels of free radicals and chromosomal aberrations. The placenta is essential for fetal programming since it determines the growth, development and health of the growing fetuses. Understanding environmental exposure on placental development and its functions helps to identify molecular mechanisms that have both early- and long-term effects on health of the fetus. A recent study from our laboratory on the human term placenta revealed a positive correlation between Cr burden in the placenta and oxidative stress. Moreover, increase in Cr burden decreased antioxidant proteins and elevated apoptotic protein sex-dependently (Banu et al., 2017).

Copper

Copper (Cu) is an essential trace metal. The majority of plasma Cu is transported bound to ceruloplasmin (>75%), whereas the remainder is bound to albumin, transcuprein, and Cu-amino acid complexes. The concentration of free Cu ions in human plasma is

10^{-13} M. Cu bound to these carriers is less tightly bound and is exchangeable. Cu is a component of a number of metalloenzymes, including cytochrome C oxidase, superoxide dismutase, glutathione peroxidase and transferase, tyrosine, dopamine β -hydroxylase, amino oxidase, lysyl oxidase, ceruloplasmin, and enzymes of fatty acid metabolism.

Cu is essential for normal reproduction, however, over exposure can cause various toxic effects. Cu is toxic in its unbound form, and causes redox imbalance due to its highly redox active nature. Prolonged use of Cu intrauterine devices (Cu-IUDs) cause a wide spectrum of adverse side effects on surrounding tissues due to long-term proximity with local tissue. Cu concentrations of uterine washings were 0.7 and 0.9 mg/L for IUD nonusers, while those with T-380A IUDs showed concentrations that varied according to their menstrual cycle (i.e., proliferative phase: 5.9 ± 1.8 ; secretory phase: 10.4 ± 4.9 and menstruation: 12.6 ± 5.4 mg/L) (Arancibia et al., 2003).

Iron

Iron (Fe) is a metallic element that makes up about 5% of the Earth's crust. Water hardness and acidity influence the amount of iron that dissolves during the percolation process in the water cycle. These iron-rich waters recharge surface waters and aquifers that inevitably serve as drinking water sources. Corrosion can often be a source of iron in drinking water. Iron contamination as a result of corroded pipes is a common occurrence in many cities with old water systems.

Increased Fe intake increases fertility levels in women. However, overexposure is detrimental to the reproductive health of the women. A previous study evaluated the effect of iron burden on hypogonadism and diminished ovarian reserve and on infertility in women with thalassemia major (TM). Iron burden in the ovary of these women had an inverse correlation with antimüllerian hormone levels and nontransferrin bound iron. An increase in reactive oxygen species and lower enzymatic antioxidant defense mechanisms have been shown to accelerate follicle aging. High redox activity in the ovarian follicular fluid, increased oxidative injury and low levels of antioxidants were reported in the ovary of a woman with TM.

Overweight and obese women with PCOS have increased serum ferritin levels indicating increased iron stores. In PCOS patients, increased iron stores contribute to insulin resistance and hyperinsulinemia. During follicular atresia and luteal regression, heme oxygenase-1 (HO-1), an enzyme-catalyzing heme degradation, was observed in apoptotic granulosa cells in atretic follicles (Harada et al., 2004) resulting in the release of iron ions from heme structures. Free iron ions, particularly ferrous iron, increase free radical generation resulting in oxidative damage. Increased iron uptake associated with the iron storage disease hemochromatosis is also associated with a higher incidence of ovarian cancer. The frequency of two mutations (C282Y, H63D) in heterozygous carriers of the hemochromatosis gene was assessed in 677 women consisting of 80 controls, 124 benign, 96 with low metastatic potential and 264 women with invasive ovarian tumors. The proportion of women with a single allele of the C282Y mutation was significantly elevated in women with benign tumors and ovarian cancers (8%–9%) compared with the control group (2.5%). This was reflected in a 4.9-fold increase in the risk of developing ovarian cancer. Survival rates for women with high-grade serous ovarian cancer with the heterozygous C282Y mutation were reduced from 39 to 19 months (Gannon et al., 2011). It is evident from the above reports that increased iron burden is deleterious to the ovary, and could predispose women to development of ovarian cancers.

Lead

Lead (Pb) is a ubiquitous environmental and industrial pollutant. Pb concentrations have increased in the atmosphere as a consequence of extensive industrialization and environmental pollution. In human studies, women occupationally exposed to Pb revealed increased incidence of spontaneous abortion, decreased birth weight and minor congenital malformations in their babies, infertility, and changes in ovarian function. When granulosa cells of women (in vitro fertilization/embryo transfer patients) were treated with Pb in vitro, Pb significantly decreased progesterone levels. This study also detected Pb in the follicular fluid of human ovary. This finding proves that Pb is able to enter the ovary and accumulate in the ovarian compartment. In occupationally exposed humans, decreased plasma levels of LH have been found. Pb also increased MMPs and decreased TIMP2 in human placenta with increased Pb burden (Paksy et al., 2001).

Manganese

Millions of kilograms of manganese (Mn) are released into the air and surface waters each year in the United States. Mn may also be released to the environment through the use of MMT (methylcyclopentadienyl manganese tricarbonyl) as a gasoline additive. Human exposure to Mn is widespread. In mammalian cells, Mn causes DNA damage and chromosome aberrations. Large amounts of Mn affect fertility in mammals and are toxic to the embryo and fetus (Colomina et al., 1996). Mn is a component of the mitochondrial enzymes, pyruvate carboxylase, superoxide dismutase (MnSOD), glutamine synthetase, alkaline phosphatase, and arginase. Mn also activates several enzymes. MnSOD, also known as SOD2, is a mitochondrial enzyme with potent antioxidant activity. Mn is an antagonist of iron and can replace Mg^{2+} in certain enzymes. Because of its similar ionic radius Mn can also interfere with the metabolism of calcium. Therefore, it is possible that Mn could induce early menarche in women. However, information is lacking on the direct toxic effects of Mn on the ovary in human. Early studies from Dees' laboratory reported direct effects of Mn on the hypothalamus, follicular development, and steroidogenesis in the ovary (see Table 1). In addition, umbilical cord blood concentration of Mn is directly correlated with intrauterine growth restriction in newborn children compared to newborns appropriate for gestational age (Vigeh et al., 2008).

Mercury

The three most common forms of mercury (Hg) (elemental, inorganic, and methylmercury) can produce adverse health effects at sufficiently high doses. The USEPA has determined that eating Hg-contaminated fish is the primary route of exposure to Hg for most people. Methylmercury is the most toxic form. It affects the immune system, alters genetic and enzyme systems, and damages the nervous system. Methylmercury is particularly damaging to developing embryos, which are 5–10 times more sensitive than adults. Elemental mercury, Hg(0), the form released from broken thermometers, causes tremors, gingivitis, and excitability when vapors are inhaled over a long period of time. Once in surface water, Hg enters a complex cycle in which one form can be converted to another. Hg attached to particles can deposit in sediment where it can diffuse into the water column, get resuspended and buried by other sediments, or be methylated. Methylmercury can enter the food chain or it can be released into the atmosphere by volatilization. Intracellular Hg is rapidly oxidized by cytosolic catalase to mercuric Hg (Hg^{2+}), the reactive species for most Hg compounds. Hg^{2+} can be formed by oxidation of Hg, reduction of mercuric salts, or demethylation of methylmercury. Hg^{2+} is highly reactive and rapidly combines with intracellular ligands such as sulfhydryls, potentially disrupting enzymes and proteins. Epidemiological studies indicate that occupational exposure to Hg in women resulted in abnormal menstrual cycles in terms of bleeding pattern and cycle length (Rodríguez-Villamizar et al., 2015). Dental assistants exposed to Hg vapor experience decreased fertility.

Nickel

The most probable route of nickel (Ni) exposure from hazardous waste sites would be from consumption of contaminated drinking water, inhalation of dust, dermal contact with bath/shower water, soil, or dust, and ingestion of Ni-contaminated soil. Groundwater contamination may occur where the soil has a coarse texture and where acid waste, such as waste from plating industries is discarded. Ni(II) may induce genotoxic effects such as DNA-protein crosslinking, DNA strand breaks, sister chromatid exchange and oxidative DNA base damage, including the mutagenic 8-oxo-29-deoxyguanosine and other lesions in CHO cells (Kasprzak, 1995). Ni^{2+} was found to be cytotoxic at 62.5 μM in primary cultures of granulosa cells from women (23–37 years of age) who undergo in vitro fertilization. Ni^{2+} decreased human chorionic gonadotropin (0.1 IU/mL hCG) or dibutyryl cyclic adenosine monophosphate (1 mM db-cAMP)-induced progesterone production. Women working in a metal refinery in Northwestern Russia were reported to have spontaneous abortions, and the newborns of the Ni-exposed women suffer from congenital musculoskeletal defects, and perinatal mortality (Vaktskjold et al., 2008).

Selenium

The trace element selenium (Se) was discovered in 1817 by the Swedish physician and chemist Berzelius; however, its essentiality in mammals was not discovered until the 1950s. Se is found in highest amounts in organ meats, such as kidney and liver, while some seafood contains nearly as much. Se is initially taken up from the soil and concentrated by plants; it is absorbed in the small intestine and incorporated into proteins. At least 25 selenoproteins including the glutathione peroxidases (GPX), thioredoxin reductases, and deiodinases contain Se. Selenoproteins play an important role in many biological functions, such as antioxidant defense, formation of thyroid hormones, DNA synthesis, fertility, and reproduction.

Se is used in animal husbandry as an essential supplement for successful reproduction. Of particular importance to reproduction and pregnancy are the GPXs, in which Se is an important component. Few clinical studies in patients with unexplained infertility revealed decreased Se in serum and follicular fluid samples. Women with polycystic ovary syndrome (PCOS) had decreased levels of Se relative to the control group, indicating that this element may play a role in the pathogenesis of PCOS related to hyperandrogenism (Coskun et al., 2013). Interestingly, women presenting with unexplained infertility or premature ovarian failure were found to have significantly increased serum levels of the ovarian autoantibody against Se-binding protein-1. Se accumulates in granulosa cell layers of large healthy follicles. Increased Se in these cells is attributed to increase in GPX1. In another study, human cumulus cells derived from cumulus-oocyte complexes collected for both in vitro fertilization and intracytoplasmic sperm injection revealed a positive correlation between GPX1 and successful fertilization and pregnancy (Ceko et al., 2015). This suggests a strong role for GPX1, and Se indirectly, in determining follicle growth, maturation, and dominance in both the cow and in women leading to specific dietary recommendations for Se for improved fertility. Thus, Se plays a significant role in female reproductive function. Because of its contribution to the formation of selenoproteins combined with its antioxidant action, a low Se status in the body results in low resistance to free radical damage. Unfortunately, studies related with Se and female reproduction are very few compared to studies in male species. More studies are needed to fill this gap in understanding the importance of Se in female reproduction.

Titanium

Titanium oxide (TiO_2) nanoparticles are used for protection against UV ray exposure due to their high refractive index. Many sunscreens contain TiO_2 as well as surface coating products which are colorless and reflect and scatter UV rays more efficiently than larger particles. Some types of TiO_2 nanoparticles have been reported to cause toxicity in vitro and in vivo, attributed to the generation of reactive oxygen species (ROS) resulting in apoptosis, micronuclei formation (Rahman et al., 2002), mitochondrial

abnormalities and other forms of cell toxicity. CHO cells treated with nano-TiO₂ rapidly formed extracellular aggregates with dimensions that were generally > 100 nm. Aggregates were readily internalized by CHO cells and appeared in vacuoles taken up by a phagocytotic or endocytotic process. Internalized aggregates were restricted to the cytoplasm and were not localized to any specific organelles or intracellular sites. Exposure to TiO₂ (5 and 200 nm size) increased the production of reactive oxygen species in both short- and long-term exposures (Thomas et al., 2011). Superoxide dismutase quenched the ROS signal produced by nano-TiO₂ of human hepatocytes. There are no studies indicating deleterious effects of Ti on the human ovary. More studies are needed to address the effects of Ti on ovarian development and function.

Zinc

Due to its nature as an essential trace element, oral uptake of small amounts of zinc (Zn) is essential for survival. The recommended dietary allowance (RDA) for zinc is 11 mg/day for men and 8 mg/day for women. Lower Zn intake is recommended for infants (2–3 mg/day) and children (5–9 mg/day) because of their lower average body weights. Oral uptake of Zn leads to absorption throughout the small intestine and subsequent distribution occurs via the serum, where it predominately exists bound to several proteins such as albumin, α -microglobulin, and transferrin. Inhalation of Zn-containing smoke generally originates from industrial processes like galvanization, primarily affecting manufacture workers. Uptake of large doses of supplemental Zn over extended periods is frequently associated with Cu deficiency. This correlation seems to be caused by the competitive absorption relationship of Zn and Cu within enterocytes, mediated by metallothioneins (MT). The expression of MT is upregulated by high dietary Zn content, and MT binds Cu with a higher affinity than Zn. Zn is a component of > 300 enzymes and an even greater number of other proteins, which emphasizes its indispensable role for human health. The cellular homeostasis of Zn is mediated by two protein families; the Zn-importer (Zip; Zrt-Irt-like proteins) family, containing 14 proteins that transport Zn into the cytosol, and the Zn transporter (ZnT) family, comprising 10 proteins transporting Zn out of the cytosol. The same transporter families also regulate the intracellular distribution of Zn into endoplasmic reticulum, mitochondria, and Golgi. In addition, many mammalian cell types also contain membrane-bound vesicular structures, so-called zincosomes. These vesicles sequester high amounts of Zn and release it upon stimulation, for example, with growth factors. Optimal nucleic acid and protein metabolism, as well as cell growth, division, and function require sufficient availability of Zn. Zn acts as a co-factor for at least 200 enzymes, including carbonic anhydrase enzymes and Cu/ZnSOD. It also stabilizes DNA conformation through its involvement in numerous DNA repair enzymes, especially important during early embryogenesis. Through its association with Zn finger proteins, it is involved in the regulation of gene expression and control of apoptosis.

Zn seems to have a pivotal role in reproduction and thus fertility via mechanisms that control genome stability. It is an important co-factor in the folate cycle, involved in the recycling of homocysteine to methionine, both of which have a major influence on methylation reactions through S-adenosyl methionine (SAM). SAM is formed in the oocyte and homocysteine impairs both methionine incorporation and normal methylation reactions. Moreover, human oocytes have a very limited capacity for homocysteine recycling, because the cystathionine β synthase (CBS) pathway is absent and the betaine homocysteine methyltransferase (BHMT) pathway, which is Zn dependent, is poorly expressed. Zn also has an important role in preventing generation of reactive oxygen species (ROS) during the first embryonic cleavage division. ZnSOD, located in the cytoplasm, is found in human oocytes and fallopian tubes and in the environment of the preimplantation embryo. Zn is present throughout the embryo's journey in the oviduct. In vitro, nonphysiologically high Zn concentrations may have negative effects on preimplantation development (Stephenson and Brackett, 1999).

Heavy Metal Toxicity: Mechanism of Action and Possible Intervention

Commonly used metals such as Fe, Cu, Cd, Cr, Hg, Ni, Pb, and As possess the ability to generate free radicals, resulting in depletion of enzyme activities, damage to lipid bilayer and DNA (Stoys and Bagchi, 1995). There are a wide variety of oxygen-, carbon-, sulfur-, and nitrogen-radicals, originating not only from superoxides, hydrogen peroxide, and lipid peroxides but also from chelates of amino acids, peptides, and proteins complexed with the toxic metals. The resulting oxidative stress may affect the levels and functions of redox-sensitive signaling molecules such as AP-1, NF- κ B, and p53, derange the cell signaling and gene expression systems, and/or induce apoptosis. Both AP-1 and NF- κ B are considered stress response transcription factors that govern the expression of a variety of proinflammatory and cytotoxic genes (Hu et al., 2002). The heavy metals have electron-sharing affinities that can result in the formation of covalent attachments mainly between heavy metal and sulfhydryl groups of proteins. Several enzymes in antioxidant defense systems may protect the proper balance between pro-oxidant and antioxidant species but unfortunately, enzymes contain sulfhydryl groups which can bind metal ions at their active sites, and hence, become inactive due to direct binding of metal ions to sulfhydryl groups. GSH is found in mammalian tissues at millimolar concentrations. The oocyte has a GSH concentration of 10 mM which accounts for > 90% of total nonprotein sulfur. Pb is known to deplete GSH levels. Zn can be replaced by Pb which inactivates the function of several Zn-dependent enzymes. The antioxidant enzymes SOD, catalase and GPX are potential targets of Pb. Se is essential for GPX activity, and Pb forms a complex with Se and decreases GPX activity. Pb inhibits heme synthesis. Because catalase is a heme-containing enzyme, Pb decreases its activity. Pb also replaces Cu and Zn, thus, decreasing the activity of Cu/Zn SOD. Therefore, inhibitory effects of metal ions such as Pb and Cu on various

enzymes impair antioxidant defense mechanisms by cells and render them more vulnerable to oxidative stress. An important property of Se is its interaction with other elements including As, Cu, Ni, Co, Cr, Mn, Zn, Cd, Sn, Pb, Hg, Bi, Mo, Ag, Au (Banu, 2013). The sequestration of elements by Se represents an efficient natural detoxification mechanism for some of these elements but also results in the physiological inactivation of Se. Se is essential for cellular antioxidant defense systems to scavenge free radicals. Supplementation of Se or Zn mitigated or inhibited the deleterious effects of Cd in causing follicular atresia in Japanese quail. Therefore, supplementation of an additional dose of Se and/or Zn (other than the dietary level) could help mitigate Cd toxicity, or other metal toxicities that respond to Se or Zn supplementation. Free radicals generated by As lead to the activation of oxidative signaling pathways that result in cell apoptosis. Supplementation of vitamins C and E alter the extent of DNA damage by reducing TNF- α levels and inhibiting activation of the caspase cascade in As-intoxicated animals. A combination of vitamin C and thiamine was effective in reducing Pb levels in blood, liver, and kidney. α -Lipoic Acid (LA) is an endogenous thiol antioxidant, which possesses the potential to quench ROS, regenerate GSH, and chelate metals such as iron, Cu, Hg and Cd. LA is also known to mediate free-radical damage in biological systems (Gorąca and Asłanowicz-Antkowiak, 2009). LA is readily available in the diet, absorbed through the gut, and easily passes through the blood-brain barrier. Exogenous supplementation with LA has been reported to increase unbound LA levels, which can act as a potent antioxidant and reduce oxidative stress both in vitro and in vivo (Bustamante et al., 1998). LA serves as a protective agent against Cd-induced membrane damage and cell dysfunction in hepatocytes. Another hormone with antioxidant properties is melatonin. Melatonin stimulates several antioxidant enzymes including glutathione reductase, GPX and SOD, promotes quick disposal of H₂O₂, enhances the production of enzymes that are involved in the synthesis of GSH, and prevents the reduction of membrane fluidity caused by lipid peroxidation. In this way, melatonin helps in scavenging free radicals. Thus, it could be a possible intervention against metal toxicity, along with other candidates such as Zn, Se and LA.

In conclusion, prenatal exposure to heavy metal EDCs is a growing concern, because such exposures have been shown to be associated with a variety of pregnancy complications as well as developmental deficits and birth defects. One of the major consequences of heavy metal exposure is increased oxidative stress and decreased levels of antioxidants (Fig. 1). Experimental data document various female reproductive dysfunctions due to metal exposure (Table 1). As heavy metals enter the water supply by numerous routes, strategies must be identified and validated to mitigate the adverse effects of metal exposure. Additional research is also needed to delineate the molecular mechanisms underlying heavy metal-induced reproductive and developmental toxicity.

Fig. 1 A schematic diagram of heavy metals-induced female reproductive disorders. (1) Heavy metals enter into a cell by active transport or passive diffusion, which results in the (2) generation of large amount of free radicals or reactive oxygen species (ROS). ROS deplete antioxidants (AOX) and AOX quenches ROS. (3) Increased oxidative stress generated by ROS changes mitochondrial membrane permeabilization. (4) Release of cytochrome *c* from the mitochondria and (5) activation of caspases, lead to (6) apoptosis. (7) Heavy metals also cause epigenetic modifications. (8) All these events culminate in several reproductive and pregnancy disorders in women, as well as intrauterine growth restriction in children. *IUGR*, intra uterine fetal growth restriction. Modified from Banu, S. K. (2013). Heavy metals and the ovary. In: Hoyer, P. B. (ed.) *Ovarian toxicology*. (2nd ed.), pp. 191–228. CRC Press.

Acknowledgement

Most of the data on chromium and the ovary and placenta from the author's laboratory were generated and published with the funding support from the National Institute of Health (NIH)/National Institute of Environmental Health Sciences (NIEHS) grants ES016605-A2 and ES020561-01. The authors acknowledge Dr. Robert C Burghardt, Professor & Associate Dean for Research and Graduate Studies, College of Veterinary Medicine & Biomedical Sciences, Texas A&M University, for his editorial comments.

General Female Reproductive Physiology

The mammalian ovary is the female gonad and has two major functions: germ cell and sex steroid hormone production. The ovarian follicular structures are the functional units in which the oocyte (female gamete) is surrounded by granulosa cells, and eventually also by theca cells. Interaction and communication between the granulosa cell layer and oocyte maintains oocyte viability, while 17β -estradiol (E_2) production within the dominant follicles requires interaction between the granulosa and theca cells.

There are a variety of different developmental stage follicles within the ovary, the most immature of which is the primordial follicle. The ovary is endowed with a finite number of primordial follicles at birth, and within the primordial follicle structure, the meiotically-arrested oocyte resides and is surrounded by squamous granulosa cells (Hirshfield, 1991). Upon receiving an activation signal, primordial follicles mature through primary, secondary, and antral follicle stages during which the number of granulosa cells increase, and they become cuboidal in structure. A tertiary follicle is characterized by the presence of a fluid filled sac, or antrum. The antrum is located between the granulosa cell layer and the oocyte and contains follicular fluid. The composition of follicular fluid arises from filtered blood running through the thecal capillaries (Shalgi et al., 1973). Ovulation occurs when a follicle ruptures and the oocyte released. Cumulus granulosa cells may be ovulated along with oocyte. The oocyte remains arrested at prophase I of meiosis until the luteinizing hormone (LH) surge, just prior to ovulation, at which time, the first polar body is extruded and the first round of meiosis is completed. The oocyte is then arrested at metaphase II until fertilization occurs. At this point, the second polar body is extruded and meiosis II is completed. Although follicular growth and development is well characterized, the mechanisms, and signals initiating follicular growth and selection as well as maintenance or regression are still not fully understood. After ovulation, a corpus hemorrhagicum forms due to luteinization of the granulosa and theca cells under the control of LH. This structure next becomes a corpus luteum (CL) which is the site of progesterone (P_4) production. The CL is the primary source of P_4 during the luteal phase of the cycle and is maintained on the ovary if the animal is pregnant and is essential for pregnancy maintenance, inhibits the hypothalamic-pituitary-ovarian axis and is involved in mammary gland preparation for lactation, though in the majority of species, placental takes over from luteal P_4 production as gestation progresses (Fig. 1).

Female Reproductive Toxicity

Ovarian follicles at any developmental stage can be impacted by chemical exposures, resulting in negative effects on oocyte or somatic cell viability, endocrine function, ovulation, oocyte competence, and germline integrity. The reproductive impact of an ovarian chemical exposure largely depends on what follicular development stage is targeted: if primary, secondary or antral follicles are targets and damaged or deleted, temporary perturbations to reproductive function will occur since these follicles can ultimately be replaced by recruitment from the ovarian reserve. However, damage or demise of the primordial

Fig. 1 Summary of ovarian physiology. During follicular development, primordial follicles (1) are recruited to primary follicles (2) when growth is initiated. Secondary follicles (3) are characterized by at least two layers of granulosa cells (shown in blue) surrounded by theca cells (shown in purple). The tertiary follicles (4) contain an antrum filled with follicular fluid. Ultimately the oocyte is ovulated (5) and a corpus luteum forms (6) from luteinized granulosa and theca cells. Nevertheless, the majority of follicles, never reach ovulation and regress via atresia (7). 17β -estradiol is produced within the preovulatory follicle while the corpus luteum produces progesterone.

follicles represent more insidious chemical exposure effects and will lead to permanent infertility and premature ovarian senescence. Since they are irreplaceable, if depleted or hyperactivated into the growing pool, females will eventually undergo ovarian failure, commonly known as menopause in women. The postmenopausal phase of a woman's life places her at greater risk to develop cardiovascular disease, obesity, osteoporosis, Alzheimer's disease, and colorectal and ovarian cancer, thus a longer time frame spent in the postmenopausal physiological state is detrimental for general female health (Hoyer and Keating, 2014).

The level and duration of exposure to an environmental reproductive toxicant may also influence the phenotypic manifestations and effects. Chronic, low dose exposures are difficult to identify since their phenotypic display may go unrecognized for years. Selective damage of small preantral follicles would not initially be observed and raise concern until the end of ovarian function that may occur years later. Further, the developmental age of the female at which exposure occurs should be considered. During childhood and prior to puberty, there are higher numbers of primordial follicles within the ovary, ergo, a chemical exposure during this life stage may not result in the same extent of ovarian damage as might be observed postpubertally. However, damage to oocytes by chemical exposures in utero and/or during childhood years present a significant concern, since these effects would not be detected until later reproductive years at which point the impact could be permanent.

There are additional nonovarian points of action that should also be considered in female reproductive toxicity which will not be further discussed herein in interests of brevity but which include impacts on the uterus, placenta, hypothalamic-pituitary-gonadal axis, hepatic metabolism of steroid hormones and lactation to name a few (Fig. 2).

Examples of Pesticides Documented to Impact Female Reproductive Capacity

Atrazine

Atrazine (ATR) is a herbicide used to kill broadleaf plants in rural and urban environments and is widely used. ATR levels in US drinking water can exceed the drinking water criteria (Barbash et al., 2001) and human exposure has been confirmed by detection of ATR in urine samples (Curwin et al., 2007). Interestingly, when ATR levels were high in Illinois drinking water, as compared to women in Vermont (a low ATR-using state) consumption of >2 cups of unfiltered water daily was associated with increased risk of irregular menstrual periods in women (Cragin et al., 2011). In rodent in vivo studies ATR-induced effects on ovarian function have been mechanistically examined. ATR-exposed rats (100 or 300 mg kg⁻¹; oral gavage daily for 2 weeks) had reduced ovarian and uterine weights, reduced circulating E₂ levels, and lengthened estrous cycles relative to control-treated females (Eldridge et al., 1994). Another study that evaluated a range of ATR exposures (0.75–100 mg kg⁻¹ day⁻¹) and two different routes (oral gavage or dietary consumption) observed altered estrous cyclicity, and attenuated LH surge, and lower numbers of oocytes ovulated, though no impacts on fetus number were noted. Interestingly, dietary ATR exposure did not alter any of

Fig. 2 Summary of potential phenotypic outcomes of ovotoxicant exposures in females across the reproductive lifespan.

the endpoints examined (Foradori et al., 2014). Thus, the route of TAR exposure is worth considering when assessing reproductive endpoints.

A study in rats examining the impact of ATR (75 mg kg⁻¹) exposure or exposure to the ATR metabolites desisopropylatrazine (DIA) and diamino-*s*-chlorotriazine (DACT) at equimolar dosages demonstrated increased both ATR and DIA increased circulating P₄ but this effect was not observed in the DACT-treated females (Fraites et al., 2009). Cultured rat granulosa cell primary cultures had increased E₂, P₄, and cytochrome P450 19a1 (*Cyp19a1*) mRNA abundance (Tinfo et al., 2011). Evidence for adrenal P₄ production due to ATR exposure has been provided in a study where ATR was administered either in a single or multiple doses and in which P₄ was elevated, the LH surge altered and increased *Kiss1* mRNA abundance in the hypothalamus demonstrated. Also this study demonstrated eloquently that timing of the ATR exposure relative to the LH surge was importance in the physiological effects observed (Goldman et al., 2013).

Gestational exposure to ATR is also a concern and administration of ATR at the higher dose (100 mg kg⁻¹ day⁻¹) during gestation days 14–21 in rats reduced female offspring birth weight and delayed vaginal opening (Davis et al., 2011). Embryonic exposure to ATR affected meiotic processes in exposed offspring and induced oxidative stress, impacted DNA double strand break repair, as well as chromosome synapsis and crossover numbers. Coupled with the meiotic effects were a reduction in primordial follicle number and increased numbers of multioocyte follicles in ovaries of adult mice (Gely-Pernot et al., 2017). Epidemiological studies in humans which have examined ATR levels in drinking water have associated ATR exposure with increased risk for preterm birth (Stayner et al., 2017), as well as abdominal defects and gastroschisis in exposed offspring (Brender and Weyer, 2016).

In nonmammalian aquatic and avian species, ATR is strongly implicated as an endocrine disruptor and a reproductive toxicant, and as an example, a study in quail discovered that ATR exposure arrested ovarian and oviductal development and increased levels of circulating E₂, P₄, LH, and PRL while downregulated follicle stimulating hormone (FSH) and testosterone (T) (Qin et al., 2015). In addition, ATR increased the level of ovarian cytochrome P450 11A1 (*Cyp11a1*), *Cyp19a1*, 3β-hydroxysteroid dehydrogenase (*Hsd3b*), and 3β-hydroxysteroid dehydrogenase (*Hsd17b*) but decreased the estrogen receptor beta (*ERβ*) level (Qin et al., 2015).

Taken together, the literature supports that ATR as a reprotoxicant with effects on the reproductive system of mammals at many different points, and the widespread exposure to ATR is of concern.

Glyphosate

With the development of herbicide-tolerant soybeans, corn and cotton in 1996, glyphosate (GLY) use has increased dramatically over the past two decades, now accounting for 50% of total herbicide applied, equating to 155 million pounds per annum with almost 100% of wheat, corn, soybean, cotton, and potato cultivation receiving GLY treatment. Outside of agriculture, GLY is extensively utilized for weed control in home gardens, railways, and roadways, therefore, both urban and rural populations are exposed to GLY. Worryingly, GLY residues are found in food and drinking water and a recent screen of 182 individuals in 18 European Union countries detected GLY presence in 44% of urine samples (Bremen, 2013). Due to widespread use, GLY residues in waterways in the range of 10–15 µg L⁻¹ are reported (Byer et al., 2008; Struger et al., 2008). GLY is water soluble and has a half-life in soil of 2–215 days and in water of 2–91 days (Giesy et al., 2000; Battaglin et al., 2014). In United States glyphosate is detectable in 79% of waterways (Bradley et al., 2017) and there have been many recent publications on the negative effects of GLY exposure on aquatic species.

No effect of GLY on E₂ production using a standardized H295R steroidogenesis assay was observed (Hecker et al., 2011). There is, however, a growing body of scientific literature providing evidence that GLY represents a mammalian health risk. In the ovary, steroid acute regulatory protein (STAR) protein increases cholesterol translocation from the outer to the inner mitochondrial membranes; and represents the rate-limiting step in ovarian E₂ production. GLY exposure reduces STAR protein in male testicular steroidogenic leydig cells (Walsh et al., 2000), thereby potentially reducing sex steroid hormone production. Also, a placental cell line, JEG3, had lowered cell viability and microsomal CYP19a activity due to GLY exposure (Richard et al., 2005), findings that were recapitulated in a human hepatic cell line, HepG2 (Gasnier et al., 2009). Use of an embryonic cell line also found that GLY decreased cell viability and CYP19a activity (Benachour et al., 2007). In addition, cultured bovine granulosa cells had a reduction in both granulosa cell viability and E₂ production due to GLY exposure while these effects were not observed in cultured theca cells at the same concentrations of GLY (Perego et al., 2017).

In vivo experiments investigating the impact of GLY exposure on female reproductive health are limited, however, both ovarian and offspring impacts have been demonstrated. Maternal demise as a consequence of GLY exposure during gestation has been previously reported. A 50% mortality rate occurred in pregnant Wistar rats exposed from gestation day 6–15 to GLY (1000 mg kg⁻¹) (Dallegrave et al., 2003), however, the mechanisms underlying these fatalities were not explored. The Ontario farm family health study correlated GLY exposure during late pregnancy with risk of spontaneous abortion (Arbuckle et al., 2001).

There are, however, also a number of studies where gestation was completed successfully in GLY-exposed mice and rats albeit with accompanying teratogenic effects on the offspring including skeletal (Dallegrave et al., 2003), male reproductive (Dalsenter et al., 2003), hepatic enzymatic (Darwich et al., 2001), behavioral (Gallegos et al., 2016; Cattani et al., 2014), and hepatic peroxidation (Beuret et al., 2005). Neonatal exposure to a glyphosate-based herbicide (2 mg kg⁻¹ day⁻¹) on postnatal days 1, 3, 5, and 7 increased resorption sites in exposed female rats when they were experiencing gestation in adulthood. In addition, there was a decreased in levels of E₂ and P₄ receptors, and mRNAs at the implantation sites (Ingaramo et al., 2016). When adult ovariectomized rats were exposed to GLY (0.5, 5, 50 mg kg⁻¹ day⁻¹) for three consecutive days increased uterine

epithelia cell height, decreased mRNA encoding the ER alpha (ER α) and P₄ receptor (PR) were demonstrated in the luminal epithelium but increased expression in the stromal epithelium (Varayoud et al., 2017). Additionally, postnatal day 1 to postnatal day 7 rat pups exposed to glyphosate in 48 h intervals had altered expression of uterine genes, hyperplasia of the luminal epithelium and increased uterine stromal and myometrium thickness (Guerrero Schimpf et al., 2017).

While a contentious area of research, there is documented scientific data supporting that GLY has female reproductive effects, though whether these effects are observed at exposure levels reflective of human exposure levels remain unclear, thus it is currently difficult to extrapolate risk.

Methoxychlor

Methoxychlor (MXC) is an organochlorine pesticide used in agriculture and was a replacement for dichlorodiphenyltrichloroethane. MXC induces ovarian atrophy and decreases steroidogenesis. Interestingly, MXC also induces growth of the ovarian surface epithelium, contrasting with the pro-death impact on the antral follicles (Symonds et al., 2005), however, oxidative stress-induced DNA damage to these cells is observed (Symonds et al., 2008). Thus, MXC induces ovarian atresia and acts as an endocrine disruptor. Many of the data documented in this section has come from the research group of Dr. Flaws at the University of Illinois, thus if a study is not cited below, it has come from this group.

In a two-generation exposure experiment, MXC was provided to rats via the diet at 0–1500 ppm. At the higher doses, MXC reduced food consumption and body weight, lengthened the estrous cycle, negatively affected fertility parameters, had deleterious effects on implantation, reduced the numbers of implantation sites and offspring, and decreased ovarian weight. Additionally, a uterotropic effect, consistent with an endocrine disrupting effect of MXC, was noted and the female offspring had increased uterine weight (Aoyama et al., 2012). These effects were dose-dependent.

Mice exposed to MXC (64 mg kg⁻¹ day⁻¹) for 20 days had reduced primordial follicle number 30 days postdosing, but this effect was not evident after a longer postdosing timeframe (60 days). Another study has indicated reduced primordial follicle number due to MXC exposure in adult rats that received exposure during gestation, and increased abundance of the insulin-like growth factor receptor was also noted in growing follicles within these ovaries, potentially contributing to altered folliculogenesis (Ozden-Akkaya et al., 2017).

Mechanistic insights into the mode of action of MXC have been gained using both in vivo and in vitro models. MXC binds to the aryl hydrocarbon receptor (AHR) in cultured ovarian antral follicles from mice to induce atresia and inhibit antral follicle growth, and deletion of *Ahr* in mice, partially protected against the ovotoxic effects of MXC exposure. Cultured antral follicles from mice exposed to MXC had a temporal pattern of increased abundance of mRNAs encoding pro- and antiapoptotic genes. Initially, increased Bcl-xl and Bax, as well as increased caspase were noted, which were followed by morphological observation of atresia, supporting that atresia resulted from apoptosis.

ER-mediated pathways may mediate the ovarian toxicity of MXC. Incubation of antral follicles with E₂ protected against both MXC- and HPTE-induced atresia. Further, ovarian atresia was greater in antral follicles from MXC-exposed *Er β* -overexpressing mice compared with their wild type counterparts. In *Er α* -deficient mice, higher levels of atresia due to MXC exposure were noted, likely through altered apoptosis within these follicles.

MXC also has actions via oxidative stress-induced mitochondrial damage. Reduced expression of superoxide dismutase 1 (*Sod1*), glutathione peroxidase (*Gpx*), and catalase (*Cat*) due to MXC exposure were observed, and co-treatment with the antioxidant N-acetylcysteine (NaC) prevented these impacts, supporting that MXC induced oxidative stress as a mode of action during ovarian toxicity. Alteration of cell cycle regulators may contribute to slower growth of antral follicles in mice exposed to MXC. Decreased abundance of proliferating cell nuclear antigen (PCNA), decreased *Ccnd2* and *Cdk4* was observed in the MXC-exposed ovaries. Protection from MXC-induced oxidative stress via co-treatment with NaC reversed this effect of MXC on *Ccnd2* and *Cdk4*. Similar findings were observed in the caprine ovary (Bhardwaj and Saraf, 2017) supporting that oxidative stress contributes to ovotoxicity due to MXC exposure.

MXC undergoes hepatic metabolism to 2,2-bis(*p*-hydroxyphenyl)-1,1,1-trichloroethane (HPTE) and mono-hydroxy methoxychlor (mono-OH MXC). In addition to the MXC parent compound, mono-OH MXC negatively affects steroidogenesis. Antral follicles from mice cultured in the mono-OH MXC had decreased ovarian sex steroid hormone levels, but pregnenolone supplementation blunted this effect and returned ovarian hormone to the levels of follicles cultured in vehicle control, thus the endocrine disrupting effects of mono-OH MXC may be at an early stage in ovarian steroidogenesis. Pregnenolone supplementation was, however, ineffective at reversing the pro-atretic effects of mono-OH MXC in cultured antral follicles. HPTE exposure of cultured rat granulosa cells negatively affected E₂ and P₄ through interaction of disruption of signaling via FSH signaling (Zachow and Uzumcu, 2006). In addition, HPTE inhibited cyclic AMP (cAMP) production and reduced the abundance of *Er α* and *Er β* in cultured rat granulosa cells (Harvey et al., 2015). Luteal cells had reduced P₄ formation as well as reduced *Cyp11a1* activity (Akgul et al., 2008, 2011), thus MXC can also negatively affect the luteal phase of the estrous cycle and thereby potentially impacts pregnancy maintenance.

There are also ovarian epigenetic effects of MXC exposure as evidenced by epigenetic alterations to pathways that have important roles in ovarian physiology due to gestational exposure to MXC (Zama and Uzumcu, 2013). Epigenetic alterations have been recently identified that are induced by MXC and that correlate with increased rates of renal and ovarian pathology as well as obesity in offspring that were exposed gestationally, and these effects had transgenerational patterns of inheritance (Manikkam et al., 2014).

Thus, MXC alters female reproductive function by dysregulating steroidogenesis, slowing antral follicle growth, inducing atresia and inducing epigenetic impacts due to gestational exposure.

Chlorpyrifos

Chlorpyrifos (CPF) is an organophosphate insecticide, widely used in agricultural and domestic settings. Relative to the previously discussed pesticides, less is known about female reproductive effects of CPF. In terms of ovarian exposure, in adult rats exposed to CPF (5 mg/kg/day) for 21 days orally, 0.03% of CPF was distributed to the ovary (Tanvir et al., 2016). Increased oocyte death as a consequence of CPF exposure in a dose-dependent manner was reported in cultured buffalo oocytes, along with reduced oocyte maturation, oocyte nuclear maturation, meiotic progression, fertilization, cleavage, and blastocyst development rates (Nandi et al., 2011). As a mode of action, oxidative stress has been evidenced in the ovary and brain of exposed rats, which was ameliorated by co-exposure to an antioxidant extract from ginger (Abolaji et al., 2017).

Exposure to CPF-methyl (CPM) (1, 10, and 100 mg kg⁻¹ bw day⁻¹) before mating, during mating, gestation and lactation by oral gavage decreased ovarian weight, decreased fertility, the numbers of implantations and the numbers of offspring and there was a higher number of male pups born to females who received 100 mg/Kg. The offspring were exposed until 13 weeks of age via lactation for 3 weeks and then via oral gavage. F1 pups exposed to CPM 100 mg kg⁻¹ in utero and during lactation via milk had reduced body weights. Circulating E₂, T, as well as thyroid hormone (T3 and T4) were reduced and there was a concomitant increased in thyroid-stimulating hormone (TSH) and cholesterol in F1 female rats (Jeong et al., 2006).

Adult rats exposed to CPF (0.1 and 2.5 mg kg⁻¹ day⁻¹) for 8 weeks had alterations to estrous cyclicity, with longer time spent in metestrous. As is the case for MXC, increased ovarian surface epithelium height was noted and there was increased atresia in follicles of CPF-exposed rats. In addition, the uterus had increased surface epithelium and endometrial gland epithelial heights, increased myometrial thickness and increased luminal epithelium height (Nishi and Hundal, 2013).

Gestational CPF exposure altered brain development, specifically glial and neuronal cell numbers in offspring of dams that received exposure (5 mg kg⁻¹ day⁻¹) during gestation day 13–17 (Chen et al., 2017). Epidemiological studies have indicated an association between CPF exposure prenatally in humans and arm tremor later in childhood, indicating prenatal impacts of CPF on the developing nervous system (Rauh et al., 2015). Additionally, behavioral deficits have been demonstrated in the offspring of rats who received exposure to CPF prior to pregnancy, indicating maternal germline transmission of neurological dysfunction (Grabovska and Salyha, 2015). Indeed, there is now a wealth of information supporting that CPF impacts the developing brain. The placenta may also be a CPF target as evidenced by ex vivo experiments on human placenta in which structural alterations induced by CPF were observed (Ridano et al., 2017).

Thus, although the evidence that CPF exposure negatively impacts the developing brain of offspring, the target point at which these impacts initiate are unknown, nor do we appreciate if these effects begin at the gamete level, thus there is a considerable amount of scientific investigation that is lacking on the reproductive effects of CPF.

Summary

ATR, GLY, MXC, and CPF are abundantly used pesticides for which the information on female reproductive effects are limited, though our knowledge in this research area is gaining. All of these chemicals have been detected in human bodily fluids and the scientific literature supports that exposure to these pesticides have reproductive and endocrine outcomes as well as effects on offspring. Whether they all induce epigenetic alterations to the maternal germline to facilitate transgenerational inheritance is unclear currently. There are additional pesticides that are not addressed in this article, and it should be borne in mind that pesticide exposures typically do not occur in isolation, thus combination exposure experiments are warranted to fully understand the impacts on all aspects of female reproductive physiology.

LH Luteinizing hormone
3-MC 3-Methylcholanthrene
PAH Polycyclic aromatic hydrocarbon
PI3K Phosphatidylinositol-3-kinase
PND Post-natal day
ROS Reactive oxygen species
Tp53 Tumor protein 53 (also known as p53)

Structure and Metabolism of PAHs

Polycyclic aromatic hydrocarbons (PAHs) are composed of two or more benzene rings with or without hydrocarbon side chains. The structure of BaP, a representative PAH, is shown in [Fig. 1](#). PAHs are formed during incomplete combustion of organic materials, for example, when tobacco, wood or other organic materials are burned, when foods are grilled or smoked, and when fossil fuels are combusted. People are mainly exposed to PAHs by inhalation of polluted air or tobacco smoke and by ingestion of grilled or smoked foods.

Metabolism of BaP as a representative PAH is shown in [Fig. 1](#). PAHs like BaP generally require metabolism to reactive metabolites to exert toxicity. The best studied metabolic activation pathway is the bay region diol epoxide pathway, which begins with oxidation by cytochrome P450 enzymes (CYPs) to arene oxides, which are then hydrolyzed by microsomal epoxide hydrolase to dihydrodiols, which undergo another CYP-catalyzed oxidation to form diol epoxides, such as BaP-7,8-diol-9,10-epoxide (BPDE) ([Xue and Warshawsky, 2005](#)). Radical cations of PAHs are formed via one electron oxidation catalyzed by cytochrome P450 and peroxidases ([Cavalieri and Rogan, 1995](#)). Diol epoxides and radical cations are highly reactive and form DNA adducts, which can result in mutations and carcinogenesis. In the aldo–keto reductase pathway, the dihydrodiol is oxidized by dihydrodiol dehydrogenases (aldo–keto reductases) to a ketol, which spontaneously rearranges to a catechol, which undergoes one electron oxidation to *o*-semiquinone anion radical, producing hydrogen peroxide, and a second one electron oxidation to *o*-quinone, producing superoxide anion radical ([Penning et al., 1996; Penning, 2004](#)). The *o*-quinone can undergo one or two electron reduction, setting up a redox cycle ([Penning et al., 1996; Penning, 2004](#)). The generation of ROS in this pathway results in oxidative DNA damage, which can result in mutations if not repaired ([Xue and Warshawsky, 2005](#)). Damage to DNA and other cellular macromolecules has been implicated in the ovarian toxicity of PAHs, as will be discussed in this chapter. The enzymes required for metabolic activation of PAHs are expressed in the ovary ([Cannady et al., 2002; Shimada et al., 2003; Rajapaksa et al., 2007](#)).

Detoxification of reactive metabolites of PAHs occurs via Phase II biotransformation pathways. Conjugation with GSH catalyzed by glutathione transferases (GSTs) is an important detoxification mechanism for quinone and diol epoxide metabolites, and glucuronidation and sulfation are important detoxification mechanisms for phenol, quinone, and dihydrodiol metabolites

Fig. 1 Metabolic activation of BaP. Key enzymes involved in formation of reactive metabolites that can react with DNA, forming mutagenic adducts include the CYPs CYP1A1, CYP1B1, and CYP1A2, epoxide hydrase, and aldo-keto reductases. The aldo-keto reductase metabolic pathway generates reactive oxygen species, H_2O_2 and $SO^{\bullet-}$.

(Swanson et al., 1986; Romert et al., 1989; ATSDR, 1995; Jernström et al., 1996; Seidel et al., 1998; Fang et al., 2002). Metabolism of PAHs by CYPs to mono-hydroxylated phenols, such as 1-, 3-, 5-, 7-, and 9-hydroxy-BaP, is considered a detoxification pathway, as these compounds do not undergo further transformation to reactive metabolites (Hecht et al., 2006). These mono-hydroxylated metabolites also undergo Phase II biotransformation and are then excreted.

PAHs enhance their own metabolic activation by binding to the ligand activated transcription factor, the aryl hydrocarbon receptor (AHR) (Shimizu et al., 2000; Denison and Nagy, 2003). AHR activation has been implicated in the ovarian toxicity of PAHs, as will also be discussed in this chapter.

Ovarian Effects of PAHs in Peripubertal Animals and Adult Animals

More than 50 years ago, it was discovered that exposure to the PAHs BaP, DMBA, and 3-MC by multiple routes induced ovarian tumors in rodents (Marchant, 1960; Mody, 1960; Biancifiori et al., 1961; Krarup, 1967). More recently, DBC was also found to

be a potent ovarian carcinogen (Buters et al., 2002; Chen et al., 2012). The initial investigators noted that ovarian atrophy, with few or no follicles remaining in the ovaries, preceded tumor formation. Detailed dose-response and time course analyses of follicle destruction by single i.p. doses of PAHs were subsequently conducted in peripubertal mice and rats (Mattison, 1979, 1980; Mattison and Thorgeirsson, 1979; Mattison et al., 1980). A strong species difference in sensitivity to primordial/primary follicle destruction was noted with mice being considerably more sensitive than rats (Mattison, 1979). Among mouse strains tested, C57BL/6 was more sensitive than DBA/2 N (Mattison and Thorgeirsson, 1979). Fifty percent of primordial follicles were destroyed in C57BL/6 mice at doses of 25 mg/kg BaP and 3MC and 1 mg/kg DMBA, while in DBA/2 N mice, 50% of primordial follicles were destroyed at 500 mg/kg BaP and 3MC and 10 mg/kg DMBA (Mattison and Thorgeirsson, 1979). No significant depletion of primordial follicle numbers was observed after dosing with 80 mg/kg of the lower molecular weight PAH pyrene (Mattison and Thorgeirsson, 1979). A more recent study compared the effects of repeated lower daily doses of DMBA, BaP, or 3-MC for 15 days on ovarian follicle numbers in peripubertal B6C3F1 mice and Fisher 344 rats (Borman et al., 2000). Similar to findings with single higher doses, mice were more sensitive than rats (Borman et al., 2000). Again, DMBA was the most potent destroyer of primordial follicles, followed by 3-MC and BaP. Differences were noted among the three PAHs in terms of which follicles were targeted, with BaP and 3-MC targeting only primordial and primary follicles, while DMBA in addition targeted granulosa cells of secondary and antral follicles (Mattison, 1980). With repeated dosing, depletion of primordial follicles results in eventual depletion of follicles at more mature stages of development (Borman et al., 2000).

Intraperitoneal injection of prepubertal mice with 50 mg/kg DMBA induced ovarian expression of the proapoptotic gene *Bax* and increased BAX protein in oocytes of primordial and primary follicles 24 h after injection (Matikainen et al., 2001). Similar increases in BAX protein expression were observed in xenografts of human fetal ovaries implanted under the kidney capsules of immunodeficient mice 24 h after a single i.p. dose of 50 mg/kg DMBA, and 76% of primordial follicles in the human ovarian grafts were dead or dying at 6 days after dosing, showing that human follicles are also sensitive to PAHs (Matikainen et al., 2001). The same group observed that the proapoptotic BCL-2 family gene *Bid* is induced in the ovary of prepubertal mice 24 h after i.p. injection of 50 mg/kg DMBA; however, *Bid*^{-/-} mice were equally sensitive to follicle depletion by DMBA as wild type mice (Pru et al., 2009). In contrast, expression of the tumor suppressor *Tp53* was also induced in the ovaries, and *Tp53*^{-/-} mice were completely resistant to follicle depletion by DMBA (Pru et al., 2009). The p53 protein responds to DNA damage by initiating repair pathways and if the damage is too great, initiating apoptosis (Zhou and Elledge, 2000).

Few studies have examined the effects of PAH exposure on ovarian follicle numbers in older adult rodents. Adult 8-month old mice showed similar (DBA/2N) or somewhat lower (C57BL/6) sensitivity to primordial follicle depletion by a single 80 mg/kg dose of DMBA or 3-MC compared to peripubertal mice (Mattison and Thorgeirsson, 1979). Corpora lutea numbers were dose-dependently decreased at 1 week after a single i.p. dose of BaP in C57BL/6N mice, with 50% depletion at a dose of 1.6 mg/kg (Swartz and Mattison, 1985). Corpora lutea were completely absent 1 week after doses of 50, 100 and 500 mg/kg, and even at 4 weeks, no corpora lutea were present in ovaries of mice dosed with 500 mg/kg (Swartz and Mattison, 1985). These results are consistent with lack of ovulation due to destruction of antral follicles or derangement of hypothalamic-pituitary-ovarian axis signaling. Further evidence that BaP acutely prevents ovulation comes from a study in which 7-week old female F344 rats were exposed by inhalation to BaP doses of 25–100 µg/m³ for 4 h/day, for 14 days, then paired with unexposed males (Archibong et al., 2012). Number of oocytes ovulated and litter size were significantly decreased and estrous cycle length was prolonged in the 100 µg/m³ group only (Archibong et al., 2012).

The above in vivo studies do not provide information about whether the parent compound or a metabolite is the ultimate ovotoxicant or whether metabolism occurs in the ovary or elsewhere. To address these questions, intraovarian injection of BaP and several of its metabolites was performed in peripubertal C57BL/6N, DBA/2N, and B6D2F1 mice; primordial and primary follicle counts were compared in the injected versus contralateral uninjected ovary (Takizawa et al., 1984). BaP and BaP diol were approximately equipotent within mouse strain, with C57BL/6N mice more sensitive than DBA/2N mice. BPDE was much more potent and was equipotent in all three strains. Together these data are consistent with BPDE being the ultimate ovotoxicant and with intraovarian metabolism of BaP to BPDE being most efficient in C57BL/6 mice. It is possible that the greater sensitivity of mice to the ovarian toxicity of PAHs compared to rats may be due to more efficient metabolism in the murine versus the rat ovary, but this has not been tested directly.

Ovarian Effects of PAHs in Neonatal Rodents

The ovarian effects of neonatal exposure to PAHs have been examined in several in vivo studies. Neonatal Swiss mice dosed i.p. from PND 4–10 with 1 mg/kg/day DMBA had about 50% fewer total follicles per section, decreased percentage of primordial follicles and increased percentages of activating (transitional between primordial and primary), primary, and secondary follicles (Sobinoff et al., 2011). Neonatal Swiss mice were dosed i.p. from PND 4–10 with 0, 1.5 or 3 mg/kg BaP and euthanized 24 h after the last dose (Sobinoff et al., 2012). Primordial follicle percentages were significantly and dose-dependently decreased and activating follicles increased by both BaP doses, while primary and secondary follicles were significantly increased and total follicles per section were decreased by about 50% only at the higher dose (Sobinoff et al., 2012). Thus, the sensitivity of neonatal mice to primordial follicle depletion by these PAHs appears to be similar to that of peripubertal mice (Borman et al., 2000).

Effects of PAHs in Cultured Neonatal Ovaries and Follicles

The mechanisms by which PAHs destroy follicles have been examined in follicle and ovary culture models. These studies suggest that the mechanisms differ for primordial compared to growing follicles.

Cultured Neonatal Ovaries

Because isolated primordial follicles do not survive in culture, the cultured neonatal (PND 3–4) ovary model, which contains almost exclusively primordial follicles, is often used to examine the effects of toxicants on primordial follicles. Neonatal rat and mouse ovaries can be cultured for at least 15 days, during which time some primordial follicles are activated into the growing pool, developing into primary and secondary follicles (Devine et al., 2002, 2010). Both DMBA and BaP have been shown to deplete primordial follicles in this culture system.

Consistent with the *in vivo* studies in peripubertal rodents, cultured neonatal mouse ovaries are more sensitive than rat ovaries to destruction by PAHs. Culture of B6C3F1 neonatal mouse ovaries with 12.5–1000 nM DMBA for 15d depleted primordial and primary follicles, with significant decreases at ≥ 12.5 and ≥ 25 nM DMBA, respectively (Rajapaksa et al., 2007). Time-course analyses showed that healthy primordial and primary follicle numbers began to decline after 6 h in culture with 1000 nM, and no healthy primordial or primary follicles remained after 8d of culture (Rajapaksa et al., 2007). Morphological changes consistent with apoptotic death were observed in oocytes and granulosa cells of primordial and primary follicles (Rajapaksa et al., 2007). Culture of F344 neonatal rat ovaries with 12.5–1000 nM DMBA or DMBA-DHD for 15d dose-dependently depleted primordial and primary follicles, but significant decreases occurred at ≥ 75 and ≥ 372 nM DMBA and ≥ 12.5 and ≥ 75 nM DMBA-DHD respectively (Igawa et al., 2009). Time-course analyses showed that healthy primordial and primary follicle numbers began to decline after 2d and 4d in culture with 1000 nM, respectively (Igawa et al., 2009). DMBA treatment increased microsomal epoxide hydrolase protein expression in oocytes of primordial and primary follicles and in both rat and mouse ovaries, and treatment with a microsomal epoxide hydrolase inhibitor was protective against DMBA, but not DMBA-DHD (Rajapaksa et al., 2007; Igawa et al., 2009). The greater potency of DMBA-DHD, as well as the protective effect of the microsomal epoxide hydrolase inhibitor, support earlier conclusions from *in vivo* studies (Takizawa et al., 1984) that PAH diol epoxide metabolites are the ultimate ovotoxicants. To examine effects of DMBA on large primary follicles and secondary follicles, neonatal rat ovaries were treated with 12.5 or 75 nM DMBA for 1 day and analyzed 1, 2, 4, or 8 days later (Madden et al., 2014). Primordial and small primary follicle numbers were unaffected, but large primary follicles and secondary follicles were decreased at 8 days after both doses and secondary follicles were decreased at 8 days after 12.5 nM (Madden et al., 2014).

The molecular mechanisms by which PAHs deplete primordial follicles have been examined in the cultured neonatal ovary. Culture of neonatal Swiss mouse ovaries for 4 days with 50 nM DMBA increased caspase 2 and 3 immunostaining and TUNEL labeling in granulosa cells of primary and secondary follicles, but not primordial follicles, consistent with induction of apoptosis in growing follicles, but not in primordial follicles (Sobinoff et al., 2011). In contrast, DMBA treatment increased AKT phosphorylation in oocytes of primordial follicles and significantly modulated phosphorylation of mTOR and expression of FOXO3A in primordial follicle oocytes, two downstream targets of phosphorylated AKT (Sobinoff et al., 2011). Microarray analysis of whole neonatal ovaries after 4d dosing showed upregulation of immune response signaling and follicular growth and development pathways, including mTOR, integrin-linked kinase, EIF2, and VEGF (Sobinoff et al., 2011). Similar results were reported by the same group for BaP. Microarray analysis identified alterations in expression of genes associated with follicular growth and development, DNA repair and follicular atresia, AHR signaling, and oxidative stress in ovaries cultured for 4 d with 1000 nM BaP (Sobinoff et al., 2012). Immunofluorescence of cultured ovaries showed increased PCNA protein in granulosa and oocyte nuclei of primordial follicles, consistent with activation, and increased activated caspases 2 and 3 and TUNEL in primary and secondary follicles, consistent with apoptosis, of BaP treated ovaries (Sobinoff et al., 2012). Taken together these results suggest that BaP and DMBA deplete follicles in the neonatal ovary by stimulating activation of primordial follicles and initiating apoptosis in primary and secondary follicles. PI3K is a positive upstream regulator of AKT signaling, which increases phosphorylation of AKT by phosphoinositide-dependent kinase 1 (PDK1). Therefore, the conclusions of Sobinoff and coworkers would lead one to predict that PI3K inhibition should protect against follicle depletion by DMBA. However, in cultured neonatal F344 rat ovaries, PI3K inhibitor enhanced depletion of both primordial and primary follicles by 1000 nM DMBA (Keating et al., 2009). One way to reconcile these apparently divergent findings is to posit that DMBA acts downstream of PI3K to activate AKT signaling. Alternatively, upregulation of AKT signaling may be a late effect that occurs after primordial follicles have died.

An earlier study, which compared DMBA and its metabolite DMBA-DHD, reported direct induction of apoptosis of primordial follicles in cultured neonatal ovaries (Matikainen et al., 2001). PND 4 mouse ovaries were cultured for 12, 24, 48, or 72 h with 1 μ M DMBA or 0.01, 0.1, or 1 μ M DMBA-DHD with or without the AHR antagonist, ANF. BAX protein was increased in oocytes of primordial follicles by 24 h, and this increase was blocked by ANF. Histologically apoptotic primordial and primary follicles were evident at 48 and 72 h; 1 μ M DMBA caused 50% and 0.1 μ M DMBA-DHD caused more than 75% depletion of healthy primordial follicles by 72 h, while no healthy primordial follicles were found in ovaries exposed to 1 μ M DMBA-DHD at 72 h (Matikainen et al., 2001). The requirement for AHR activation and BAX induction was further supported by showing that cultured *Ahr*^{−/−} or *Bax*^{−/−} PND4 ovaries were completely resistant to follicle depletion by 0.1 μ M DMBA-DHD. To test whether activation of the *Bax* promoter by DMBA involves AHR, oocytes from PND 12 small secondary follicles were microinjected with a *Bax*-promoter GFP reporter; 68% of wild type oocytes that were exposed to 1 μ M DMBA-DHD demonstrated *Bax* promoter activation, compared to

only 16% of similarly treated *Ahr*^{−/−} oocytes (Matikainen et al., 2001). Mutation of the two AHR response elements in the *Bax* promoter abolished the ability of DMBA-DHD to activate the promoter.

Cultured Growing Follicle

The effects of PAHs on follicular growth and apoptosis have been studied in cultured, isolated secondary and preovulatory mouse and rat follicles. BaP concentration-dependently inhibited FSH-stimulated growth and estradiol production of secondary follicles from PND 22 rats cultured for 5 days, with all concentrations, including the lowest of 1.5 ng/mL (6 nM) significantly inhibiting growth (Neal et al., 2007). The same group reported that BaP also concentration- and time-dependently inhibited in vitro maturation to the antral stage of small secondary follicles from PND 13 mice cultured for up to 12 days with LH and FSH (Sadeu and Foster, 2011). The lowest effective concentration was 45 ng/mL (180 nM). Oocyte nuclear maturation in response to hCG after 12 days of culture was not affected by BaP (Sadeu and Foster, 2011). BaP at 180 nM, but not lower, concentrations upregulated follicular mRNA expression of *Cyp11a1* and *Cyp11b1* at 8 and 12 days of culture, respectively, consistent with AHR activation (Sadeu and Foster, 2013). Expression of the proapoptotic genes *Bax* and *Hsp90ab1* was increased after 12, but not 8, days of culture (Sadeu and Foster, 2013). Levels of BPDE and BaP-7,8-quinone DNA adducts and the oxidative damage markers 8-OH-dG and 8-isoprostane increased in a BaP concentration dependent manner in follicles cultured for 13 days (Yao et al., 2017). No direct markers of apoptosis were examined in the preceding studies. DMBA concentration-dependently induced apoptosis in preovulatory Sprague–Dawley rat follicles cultured in the presence of FSH for up to 48 h; the lowest effective concentration was 1 μM (Tsai-Turton et al., 2007). ROS were increased after 12 h, followed by increased numbers of BAX-positive granulosa and theca cells at 24 and 48 h, and increased numbers of activated caspase 3 and TUNEL-positive granulosa and theca cells at 48 h (Tsai-Turton et al., 2007). Treatment with glutathione ethyl ester, a cell permeable form of GSH, protected against and depletion of GSH with buthionine sulfoximine enhanced the induction of apoptosis by DMBA. Taken together, these studies are consistent with inhibition of follicular growth and maturation and induction of oxidative stress and apoptosis of secondary and antral follicles by PAHs.

Effects of PAHs on Oocyte Quality

Oral administration of 13 mg/kg BaP to peripubertal mice resulted in DNA damage measured by the alkaline comet assay in ovulated oocytes 4 and 6 days after dosing and in cumulus cells at 2, 4, and 6 days; levels had returned to baseline at 15 days (Einaudi et al., 2014). BPDE DNA adducts in cumulus cells were significantly elevated 2, 4, and 6 days after exposure, but not at 15 and 22 days (Einaudi et al., 2014). Oocytes ovulated 4 and 6 days after exposure would have been enclosed in large secondary and small antral follicles at the time of exposure, while oocytes ovulated at 15 and 22 days would have been in primary and primordial follicles at the time of exposure and may have been more likely to have undergone atresia as a result of DNA damage. A study by another group showed that surviving oocytes that had been exposed at the quiescent primordial follicle stage had indicators of decreased oocyte quality. Postnatal mice were dosed i.p. from PND 4–10 with 0, 1.5, or 3 mg/kg BaP and were superovulated 6 week. after the last dose. Oocyte mitochondrial superoxide anion levels and oxidized lipid were dose-dependently increased, while in vitro sperm-egg binding was dose-dependently decreased (Sobinoff et al., 2012).

Effects of PAH Exposure During Prenatal Ovarian Development

Germ Cell Depletion In Vivo

Germ cells in the developing ovary that are not yet enclosed in follicles appear to be even more highly sensitive to destruction by PAHs than follicle-enclosed oocytes. Studies summarized below collectively support that induction of apoptosis of germ cells by PAHs requires AHR activation, which induces metabolism to reactive metabolites and increases expression of *Tp53*, leading to apoptosis initiation via expression of proapoptotic BCL-2 family members *Hrk* and *Bax* and activation of caspases (Fig. 2). Furthermore, Phase II metabolism and ROS detoxification by glutathione are important defenses against germ cell depletion in the developing ovary.

Oral dosing of CD-1 mice with 0, 10, 40, or 160 mg/kg BaP from gestational day 7 to 16, spanning the critical windows of primordial germ cell (PGC) formation, migration to the gonadal ridge, proliferation during migration and in the ovary, and entry into meiosis, resulted in dose-dependently decreased fertility in the F1 female offspring; all females in the 40 and 160 mg/kg groups were infertile (MacKenzie and Angevine, 1981). Very few large follicles or corpora lutea were observed in the ovaries of F1 females exposed to 10 mg/kg/day, while ovaries from the 40 and 160 mg/kg/day groups were absent or very small (MacKenzie and Angevine, 1981). Using the same dosing route and dosing window, F1 offspring of C57BL/6J female mice dosed with 2 mg/kg/day BaP, had 81% fewer primordial follicles and 66% fewer follicles of all stages than control F1 females at 6 week. of age (Luderer et al., 2017).

Depletion of fetal ovarian germ cells by DMBA requires the proapoptotic BCL-2 family protein BAX. Pregnant mice were treated with 1 mg/kg DMBA or vehicle i.p. on gestational day 14.5, and ovaries of female offspring were analyzed on PND4 (Matikainen et al., 2002). Healthy primordial follicle numbers were depleted by more than 80% in wild type mice exposed to DMBA in utero, while primordial follicle numbers were not decreased by DMBA in *Bax*^{−/−} mice (Matikainen et al., 2002).

Fig. 2 Model of activation of apoptosis in ovarian germ cells by PAHs. The model is a composite of results from in vivo and in vitro studies of prenatal and postnatal exposure to PAHs or their metabolites. PAHs are metabolically activated via the pathways shown in Fig. 1 in ovarian germ cells (blue polygon). Metabolism is enhanced by PAH binding to the AHR, which activates this transcription factor, causing it to translocate to the nucleus (red circle), where it increases transcription of CYPs that metabolize PAHs, as well as transcription of the proapoptotic gene *Bax*. Reactive metabolites and ROS cause DNA damage which increases *Tp53* expression. TP53 activates apoptosis by increasing proapoptotic BCL-2 family proteins, including HRK and BAX, leading to caspase activation, and ultimately apoptotic cell death of germ cells in the prenatal ovary or primordial follicles in the postnatal ovary.

Consistent with the important role of GSH in Phase II detoxification of PAH metabolites and in reduction of ROS generated as a result of PAH metabolism, embryos deficient in GSH due to deletion of the modifier subunit of the rate limiting enzyme in its synthesis (*Gclm*^{−/−} mice) were more sensitive to germ cell destruction by prenatal exposure to BaP. Oral gavage from GD 7–16 with 0, 2 or 10 mg/kg/d BaP of pregnant *Gclm*^{+/−} mice mated with *Gclm*^{+/−} males dose-dependently decreased fertility and ovarian follicle numbers in their F1 female offspring, with the *Gclm*^{−/−} offspring significantly more affected than their wild type littermates (Lim et al., 2013).

Ovarian follicle numbers were decreased in 3 week old offspring of C57BL/6 mothers treated preconception and/or during lactation with a mixture of 1 mg/kg BaP and 1 mg/kg DMBA in corn oil administered s.c. once a week for 3 week, followed by mating with an untreated male and/or administered on PND3 and then twice more at 1 week intervals (Jurisicova et al., 2007). Primordial and primary follicles were depleted by about 40% after either preconceptional or lactational dosing and by about 70% after treatment during both windows, and this was prevented by cotreatment with the AHR-antagonist resveratrol. Protein and mRNA expression of the BH3-only BCL-2 family member Harikiri (*Hrk*) were upregulated 24 h after culture of neonatal ovaries with 1 μM BaP and DMBA, and resveratrol prevented upregulation of *Hrk*. No significant depletion of follicles was observed in *Ahr*^{−/−} offspring of *Ahr*^{+/−} mothers treated in the same manner during both preconceptional and lactational windows, nor was *Hrk* upregulated. Upregulation of *Bax* by preconceptional and lactational administration of the PAH mixture was absent in *Hrk*^{−/−} offspring. The authors stated that the preconceptional dosing regimen did not result in any exposures during gestation. However, others have shown that PAH metabolites persist in offspring tissues for more than 2 weeks after oral or inhalation dosing (Wu et al., 2003; Archibong et al., 2012; Jules et al., 2012). Therefore, the preconceptional treatment most likely resulted in gestational exposure as well as preconceptional exposure, and one cannot exclude direct effects on the developing germ cells.

Germ Cell Depletion in Cultured Embryonic Ovaries

Cultured E13.5 mouse ovaries with attached mesonephros are an excellent model system in which to study the mechanisms of toxicity of PAHs in the embryonic ovary. E13.5 corresponds to the onset of entry of oogonia into meiosis. These studies support that germ cell destruction by PAHs at this developmental stage is apoptotic, requiring AHR-mediated increased BAX expression and caspase activation.

Culture of E13.5 ovaries with 0.01–1 μM DMBA-DHD for 72 h concentration-dependently depleted germ cells, and germ cell depletion was prevented by the AHR antagonist ANF (Matikainen et al., 2002). DMBA-DHD upregulated BAX protein in germ cells at 24 h, prior to any morphological indicators of apoptosis, and ANF also prevented the increase in BAX. Culture of E13.5 ovaries with 50–1000 ng/mL (0.2–4 μM) BaP, concentration-dependently increased BAX protein levels in germ cells at 6 h, followed at 24 h

by germ cell activation of caspase 3 and caspase 9, and at 48 h by decreased germ cell numbers (Lim et al., 2016). Treatment with a pan caspase inhibitor completely prevented germ cell depletion by BaP.

Culture of human gestational week 8–9 ovary-mesonephros complexes with 1 μ M DMBA-DHD for 7d did not significantly alter the percentage of apoptotic, activated caspase 3 positive germ cells, but decreased the percentage of proliferating, phospho-histone H3-positive germ cells (Anderson et al., 2014). Germ cell numbers were not affected, but the counts were expressed per unit area rather than per ovary, which may have obscured an effect on germ cell number. Oogonia are still proliferating and have not begun to enter meiosis during weeks 8–9 of human pregnancy. This may explain the different results observed in this experiment compared to the studies that used cultured E13.5 mouse ovaries. Alternatively, apoptotic cells may have already been cleared after 7 days of culture, and no earlier time points were examined.

Transplacental Carcinogenesis

As noted above, exposure of adult rodents to PAHs causes ovarian tumors later in life. Prenatal development appears to be an even more sensitive window for ovarian tumorigenesis induction by PAHs. Exposure from GD 7–16 via oral treatment of pregnant *Gclm*+/- mice with BaP dose-dependently depleted ovarian germ cells and induced ovarian tumors in the F1 female offspring, with more severe effects in *Gclm*-/- than *Gclm*+/+ offspring (Lim et al., 2013). All of the 10 mg/kg/d *Gclm*-/- offspring had bilateral tumors, while 50% of the 10 mg/kg/d *Gclm*+/+ offspring had unilateral tumors and 33% had bilateral tumors. In the 2 mg/kg/d exposed groups, no *Gclm*+/+ offspring had tumors, while 11% of *Gclm*-/- females had a unilateral tumor (Lim et al., 2013). No tumors in other organs were noted at these doses of BaP. Two other PAHs, DMBA and DBC have also been found to be transplacental ovarian tumorigens at doses that cause tumors in other organs. A single oral dose of 60 mg/kg DMBA at any of GDs 6, 8, and 10–20 induced malignant ovarian tumors later in life in 30%–80% of exposed offspring, with peak sensitivity on GDs 8–13 (Goerttler et al., 1981). Exposure of pregnant mice to a single oral dose of 15 mg/kg DBC on GD 17 induced ovarian tumors in about 18% of the female offspring, while four doses of 3.75 mg/kg on GD 5, 9, 13, and 17 induced ovarian tumors in about 50% (Shorey et al., 2012). These studies suggest that the window of greatest sensitivity for transplacental ovarian tumorigenesis is the embryonic period prior to entry of germ cells into meiosis.

Conclusions

The PAHs BaP, DMBA, and 3MC are potent ovarian toxicants at all developmental stages—embryonic, neonatal, peripubertal, and adult. They are metabolized to reactive metabolites that destroy germ cells in the developing ovary and primordial follicles postnatally by activation of AHR, induction of BAX- and caspase-dependent apoptosis, resulting in premature ovarian follicle depletion, reproductive senescence, and ovarian tumors (Fig. 2). These PAHs also destroy follicles at later stages of development and acutely prevent ovulation. These data from experimental studies with PAHs are consistent with epidemiological data on the effects of smoking in women, which show that smoking is associated with early menopause, decreased fecundity, and ovarian cancer in women smokers and with decreased fecundity and earlier age at menopause in daughters exposed in utero.

Estrogen Biosynthesis and Function

Estrogens are members of the steroid hormone family that play physiological roles in the development and function of reproductive and nonreproductive organs as well as pathological roles in a number of the pathogenesis such as endometriosis, polycystic ovary syndrome, and breast tumor. Estrogens are synthesized by the cells that express an enzyme, aromatase, that catalyzes the conversion of a C19-steroid precursor (androgen) to estrogen. In females, the primary sites of aromatase expression are the ovarian granulosa cells where theca cells convert cholesterol to pregnenolone, which is then further converted to androstenedione and testosterone by 17,20-lyase and 3 β -hydroxysteroid dehydrogenase (3 β -HSD) enzymes, respectively. These androgens are then transported to granulosa cells by simple diffusion and converted to estrone, or 17 β -estradiol (estradiol), the primary and most potent estrogen, by aromatase. Estrone can be converted to estradiol by the 17 β -HSD enzyme (Findlay et al., 2010). Secondary sites include adrenal glands, skin, osteoblasts, pancreas, brain, and lymph nodes. In each site of estrogen synthesis, aromatase expression is regulated by a unique promoter, while its biochemical function and estrogenic products are the same in all sites of estrogen synthesis (Kamat et al., 2002). Precursors (androgens) of estrogen synthesis are produced in some estrogen synthetic sites such as gonads, but most extra-gonadal sites use an external source of androgens as precursors as summarized in Fig. 1. In women, during pregnancy and after menopause, the placental syncytiotrophoblast and adipose tissues are considered the primary sites of estrogen production, respectively (Cui et al., 2013).

Estrogens synthesized in the ovary play a key role in folliculogenesis and steroid production within the ovary. When secreted into the systemic circulation, estrogen regulates FSH and LH release and stimulates the growth and differentiation of the uterine epithelium (Stocco, 2008). In the mammary and pituitary glands, estrogens regulate proliferation and differentiation of stromal and epithelial cells and stimulate prolactin secretion, respectively. These estrogenic actions occur during fetal mammary development, adult morpho-physiological changes, and pregnancy-associated mammary gland growth for lactation preparation (Saji et al., 2000).

Extra-gonadally synthesized estrogens play tissue-specific roles. In the adipose tissue, they modulate lipogenesis, increase high-density lipoprotein, and decrease low-density lipoprotein production. Estrogen stimulates bone formation and regulates synthesis of proteins responsible for blood clotting in the liver. Estrogens also play a neuroprotective role in the brain by modulating neuronal metabolism, pain sensitivity, and cognitive behavior. In the adrenal cortex and pancreatic cells, estrogen enhances steroidogenic activity and increases insulin expression. Estrogen synthesized in lymph nodes regulates the maturation, differentiation, and migration of monocytes, macrophages, and dendritic cells (Barakat et al., 2016).

Estrogen Receptors

Estrogens exert their actions in a target cell or tissue mostly through the activation of two estrogen receptors (ER α and ER β) encoded by the *Esr1* and *Esr2* genes, respectively. Both ERs belong to the superfamily of nuclear receptors and act as transcription factors. Estrogens can bind to these ERs with similar affinities but trigger different signaling pathways. In a cell, an estrogen-bound ER travels to the nucleus where it either stimulates or inhibits transcription of its target genes via two distinctive mechanisms. An estrogen response element (ERE)-dependent mechanism involves a direct interaction between an ER and a specific DNA sequence (ERE) of the promoter of the estrogen target gene. In this process, ER α and ER β probably interact with other transcription factors that may confer signaling specificity between the two ERs. ER may regulate gene expression via an ERE-independent pathway. Under this mechanism, an ER influences the expression of a gene by binding not to an ERE but to other transcription factors that directly or indirectly interact with DNA sequences. Stimulating protein-1 (SP-1), activator protein 1 (AP-1), nuclear factor κ B (NF- κ B), and c-Jun are known to interact with ERs (Findlay et al., 2010).

Estrogens are also known to bind to a cohort of cytoplasmic or membrane proteins that are not classical ERs. Binding of estrogens to these proteins activates a subset of different G proteins and/or protein kinase cascades, such as MAPK/ERK, PI3K/AKT, cAMP, PKA, and PKC which in turn phosphorylate substrates, including membrane-based ion channels and secondary messenger systems, leading to rapid cellular responses. This pathway is mainly responsible for the acute and rapid estrogen actions that occur much faster than transcriptional processes (Cui et al., 2013; Findlay et al., 2010).

ER Expression in Female Reproductive Organs and Impact of Losing ER in Mouse Models

A target tissue or organ responds to estrogens differently depending on the types of ERs expressed and the expression levels. In the ovary, ER α is expressed in theca and surface epithelial cells, while ER β is expressed exclusively in granulosa cells (Drummond and Fuller, 2012). This differential distribution suggests that estrogen actions in the theca cells are partly mediated by ER α , and follicle

Fig. 1 Sites of estrogen syntheses, mode of estrogen action, and targets of antiestrogens in females. Estrogens are synthesized in the ovary and a variety of extra-gonadal tissues where aromatase is expressed. Aromatase is an enzyme that converts androgens to estrogens. Once synthesized, estrogens reach their target tissues by either diffusion or circulation and exert their actions by binding to estrogen receptors (ERs) that are localized in the cell membrane (membrane-bound ERs) or nucleus (ER α and ER β). Antiestrogens inhibit estrogen production or interfere ER action, disrupting estrogen-regulated pathways or events at cell, tissue, or organ levels. Several synthetic drugs and natural products are used as antiestrogens for the purpose of inhibiting aromatase or ERs. Some endocrine disrupting chemicals (EDCs) act as antiestrogens by decreasing aromatase activity or binding to ERs.

growth and estrogen biosynthesis in granulosa cells are mediated mainly by the activation of ER β . In the uterus and oviduct, ER α is highly expressed in luminal and glandular epithelial cells and in the stroma, while ER β is found only in the endometrial glandular epithelial cells and rarely in the oviduct (Wang et al., 2000).

In the mammary gland, ER α is present in epithelial cells of intralobular acini and interlobular ducts, whereas ER β is expressed in epithelial cells as well as in the luminal and myoepithelial cells. ER α expression in a breast tumor indicates a poor prognosis (Saji et al., 2000).

Estrogens play numerous modulatory roles in the hypothalamus–pituitary–ovary axis. In the hypothalamus, both ERs are expressed in distinct patterns in each hypothalamic nuclei. In the anterior lobe of the pituitary gland, ER α is the predominant receptor, and diverse lines of evidence indicate that ER α is the major mediator of estrogen action in the pituitary. ER β expression is low in the anterior lobe but high in the posterior and intermediate lobes.

Most of the roles that estrogens play were discovered using genetically modified mice that lack either or both subtypes of ERs. The phenotype of ER α -deficient (ER α KO) mice is different from that of ER β KO mice, indicating unique pathways regulated by the two ERs as shown in Table 1. ER α KO female mice are infertile; they exhibit hyperemic ovaries with hemorrhagic follicles and do not ovulate. These ovarian defects are in part a consequence of a direct effect on theca cells and ovary function, but also a result of pituitary dysfunction. Furthermore, ER α KO female mice exhibited a hypoplastic uterus that is incapable of maintaining fetal implantation. Interestingly, mammary glands of ER α KO mice exhibited normal fetal development, but they remain rudimentary, suggesting that ER α expression is necessary for mediating growth stimulation. Previous studies show that global ER β KO females exhibit reduced fertility, mainly explained by the defects in the ovary and a marked increase in the number of premature atretic follicles (Drummond and Fuller, 2012). Nevertheless, a novel ER β KO mouse, which was generated by knock-in of codon-improved Cre recombinase (iCre) gene into the exon of the *Esr2* gene, was completely infertile in the female (Cacioppo et al., 2016). The uterus of ER β KO females is hyper-responsive to estrogens, leading to uterine dysfunction and infertility (Walker and Korach, 2004).

Table 1 Estrogen receptors in female reproductive organs and pathological abnormalities of ER-deficient mice

Organs	Sites of ER expression		Phenotypes of ERKO mice	
	ER α	ER β	ER α KO	ER β KO
Ovary	Theca and interstitial cells and germinal epithelium	Granulosa cells	Anovulation, hemorrhagic follicles	Follicle atresia, defective folliculogenesis
Uterus	Luminal, glandular epithelial cells, and stroma	Glandular epithelial cells	Hypoplastic uterus, no implantation	Hyperplastic, hypersensitive to estrogens
Mammary gland	Epithelial cells of intra-lobular acini and inter-lobular ducts	Epithelial, luminal, and myoepithelial cells	Defective myoepithelial cell layers	Hyper-proliferation of alveolar cells

Antiestrogens and Their Medical Uses

Antiestrogens are agents that either inhibit estrogen production or interfere with estrogen receptor signaling, preventing estrogen from mediating its biological effects in the body. Natural antiestrogens are often used to reduce estrogen production in women with excessive estrogen levels or with an ER-positive tumor. Of note, ER α is considered as one of the most important clinical markers in breast tumor patients and as the most successful molecular target in cancer drug discovery. Antiestrogen therapy has thus become the main approved treatment for ER α -positive breast cancer.

Commercial Antiestrogens

Estrogens stimulate proliferation and metastasis of ER α -positive breast cancer cells, making aromatase and ERs ideal targets for treating breast cancers. Therefore, antiestrogenic drugs are used for ER α -positive (and/or PR-positive), but not for ER α -negative, breast cancers. Antiestrogenic drugs are administered before surgery to reduce tumor size and/or after surgery to suppress the proliferation of remaining cancer cells (Mallick et al., 2016). Selective estrogen receptor modulators (SERM) are used for targeting ERs and aromatase inhibitors for decreasing estrogen synthesis. Table 2 lists antiestrogenic medications, their modes of actions, and possible side effects.

Tamoxifen

Tamoxifen is the most widely used SERM that acts as agonist and antagonist in a tissue-selective manner. Tamoxifen is metabolized to endoxifen, a bioactive form, in the liver by cytochrome p450 enzymes. It exerts an antiestrogenic effect in the breast by inhibiting ER α signaling but a proestrogenic effect by promoting cell proliferation in the uterus, brain, and bone (Robertson, 2004). Tamoxifen is an FDA-approved drug for treatment of all stages of breast cancer. However, because tamoxifen acts as an ER α agonist in the uterus, prolonged exposure to this SERM increases the risk of developing endometrial cancers. Tamoxifen alters the plasma protein profile by increasing sex hormone-binding globulin and antithrombin III, whose expressions are regulated by estrogens. Tamoxifen treatment of breast cancer often continues for 5 years. Use of tamoxifen decreases the bone density as it leads to decreases in markers of bone turnover (serum osteocalcin and urinary N-telopeptide). This prolonged treatment leads to a number of side effects such as sweating, hot flashes, vaginal discharge, vaginal dryness, itching, and depression.

Raloxifene

Raloxifene is an SERM that has an antiestrogenic effect similar to tamoxifen, as it has antiestrogenic effects in breast and proestrogenic effects in the uterus, brain, and bone. This drug is metabolized in the gut, but it does not require a cytochrome enzyme. Moreover, raloxifene has greater affinity for the estrogen receptor than tamoxifen; it has greater estrogenic effects on bone and lesser

Table 2 Antiestrogenic medications, their modes of actions, and associated side effects

Antiestrogens	Drug name	Mode of action	Side effects
Selective estrogen receptor modulators (SERMs)	Tamoxifen, raloxifene, toremifene	ER α antagonist in mammary cells; ER α agonist in the endometrium	Fatigue, hot flashes, vaginal dryness, mood swings, mental impairment, blood clot, increased risk of endometrial cancers
Nonsteroidal aromatase inhibitors	Anastrozole, letrozole	Inhibit aromatase enzyme activity; inhibit estrogen synthesis	Gastrointestinal disturbances, hot flashes, muscle pain, joint stiffness and/or pain, osteoporosis
Steroidal aromatase inhibitors	Exemestane		
Others mechanism of actions	Fulvestrant	Block estrogen receptors and eliminate them temporarily	Hot flashes, night sweats, mild nausea, fatigue, osteoporosis

estrogenic effects on the uterus compared to tamoxifen (Mallick et al., 2016). Raloxifene displays many of the same side effects as tamoxifen when used for an extended period of time.

Toremifene

Toremifene is another SERM that has an action mode similar to tamoxifen. This drug was developed as an alternative to tamoxifen with the hope that it would produce fewer uterine side effects. However, the side effects of toremifene treatment are similar to those of tamoxifen treatment (Robertson, 2004). Toremifene is used less frequently and is approved only to treat metastatic breast cancer.

Anastrozole

As a pure antiestrogen, this drug produces antiestrogenic effects in any estrogen-responsive tissues including breast and uterus. Anastrozole is a nonsteroidal aromatase inhibitor that reversibly binds to the aromatase enzyme and suppresses estrogen synthesis. This drug is used for treating ER-positive breast cancer and is also used as a measure for preventing breast cancer development in women at high risk. Anastrozole is preferred over tamoxifen for treating postmenopausal women with localized breast cancer because of its good safety profile for postmenopausal women as well as younger women. Side effects include hot flashes, altered mood, joint pain, nausea, osteoporosis, and rheumatic disorders.

Letrozole

Letrozole is a nonsteroidal aromatase inhibitor that reversibly binds to aromatase enzyme, and inhibits estrogen synthesis. It is used for treating ER α -positive local or metastatic breast cancer in postmenopausal women. Letrozole is also used to induce ovulation in women who exhibit polycystic ovary syndrome or anovulation. When the enzyme aromatase is inhibited by letrozole, estrogen levels are attenuated. This results in the increased output of FSH from the brain and pituitary gland, which induces the development of a mature follicle in the ovary and ovulation. The most common side effects of letrozole are sweating, hot flashes, joint pain, and fatigue.

Exemestane

Exemestane is used for the adjuvant treatment of postmenopausal women with ER α -positive breast cancer who have received 2 to 3 years of tamoxifen treatment for the completion of 5 consecutive years of hormonal therapy (Mallick et al., 2016). Because this steroidal aromatase inhibitor irreversibly binds to the active site of the aromatase enzymes, preventing them from converting androgens into estrogens, it is contraindicated in premenopausal women. The most common side effects are hot flashes, sweating, insomnia, headache, and joint pain. Nausea and fatigue are observed mainly in patients with advanced breast cancer.

Fulvestrant

Fulvestrant is an estrogen receptor antagonist that competitively binds to the ER α with a much greater affinity than tamoxifen. This drug is not an SERM, as it acts like an antiestrogen throughout the body. In addition to blocking the estrogenic effects of estradiol, fulvestrant has no estrogenic effects on the endometrium. Fulvestrant is used in postmenopausal women with ER-positive breast cancer. Prolonged treatment with fulvestrant causes side effects such as hot flashes, osteoporosis, mild nausea, and fatigue (Robertson, 2004).

Natural Products as Antiestrogens

Many natural molecules present in plants have estrogenic and/or antiestrogenic mimetic activities. Plants produce a wide variety of secondary metabolites, some of which are phytoestrogens that have chemical structures that are similar to estrogens and display estrogenic activity (Liu et al., 2010). Exposure to phytoestrogens occurs primarily through dietary intake. Most of phytoestrogens have antiestrogenic properties that may make them effective therapeutic agents. Therefore, blocking the activity of ERs in the signal transduction pathway is important for reversing the development of estrogen-responsive diseases such as cancer. Furthermore, some phytoestrogens are used as an effective treatment for breast cancer because of their apoptotic properties and antiestrogenic effects. However, phytoestrogen therapy is safe only for postmenopausal women because they have lower estrogen levels in their bodies (Lecomte et al., 2017). This therapy can also be used conjunctively with antiestrogenic drug therapies. Phytoestrogens can also act as endocrine disruptors by affecting estrogen biosynthesis. Isoflavones, flavones, lignans, coumestans, and mycoestrogens are representative phytoestrogens (Table 3).

Isoflavones

Isoflavones are widely consumed phytoestrogens such as genistein, equol, daidzein, biochanin A, and formononetin. They are found in soybeans, red clover, certain fruits, legumes, and nuts. They have a weak inhibitory activity on aromatase enzyme and a strong inhibitory activity on 3 β -HSD and 17 β -HSD (Sifakis et al., 2017). Soybeans are the most recognized sources of phytoestrogens as they are rich in genistein and daidzein contents. Isoflavone supplements that containing predominantly genistein are often used in dietary supplements for reducing hot flashes in postmenopausal women. Intake of isoflavone-rich food or dietary supplements seems to lower the incidence of breast cancer and osteoporosis in postmenopausal women. Moreover, genistein can compete against estrogen and bind to both estrogen receptors with a much higher affinity toward ER β than ER α . It has been

Table 3 Exemplary phytoestrogens, dietary sources, and their mode of action

Groups	Phytoestrogens	Dietary source	Mode of action
Isoflavones	Genistein, equol, daidzein, biochanin A, formononetin	Legumes, soybean, nuts, red clover	Inhibit 3 β -HSD and 17 β -HSD; inhibit aromatase enzyme
Flavones	Apigenin, chrysin, quercetin, kaempferol	Mostly red and yellow fruits and vegetables	Potent inhibitors of 17 β -HSD and aromatase enzyme; inhibit 3 β -HSD
Flavonones	Flavanone, naringenin	Citrus fruits	Potent inhibitors of 17 β -HSD and aromatase enzyme; inhibit 3 β -HSD
Lignans	Enterodiol, enterolactone	Most fruits, cereals, vegetables, flaxseed, sesame seed	Weak inhibitor of aromatase enzyme
Coumestans	Coumestrol	Spinach, bean shoots, clover, Alfalfa sprouts, sunflower seeds	Inhibit 17 β -HSD; inhibit aromatase enzyme; higher binding affinity to estrogen receptors
Mycoestrogens	Zearalenone	Mold on bread and plants	Higher binding affinity to estrogen receptors; inhibit 17 β -HSD

identified as an angiogenesis inhibitor because it inhibits the proliferation and survival of cancer cells. In addition, moderate doses of genistein inhibit cell proliferation on cancers of the prostate, cervix, brain, breast, and colon (Spagnuolo et al., 2015).

Flavones and flavonones

Flavonoids are natural products that are widely distributed in the plant kingdom and categorized according to their molecular structures as flavones, flavanones, catechins, and others. Flavones are a class of flavonoids that includes apigenin, chrysin, quercetin, and kaempferol. Flavones are present mainly in cereals, red and yellow fruits, and vegetables (Liu et al., 2010). Flavones and flavonones appear to be more potent than isoflavones in inhibiting 17 β -HSDs and 3 β -HSD. Compared with isoflavones, flavones are relatively potent inhibitors of aromatase enzyme. Flavones can be used conjunctively with antiestrogenic drug therapies, inhibiting aromatase, which is considered a major strategy in treating breast cancer patients.

Lignans

Lignans are a class of phytoestrogens that contain enterolactone and enterodiol. Enterolactone and enterodiol are formed by bacteria in the intestinal tract from the plant lignans matairesinol and secoisolariciresinol, which exist in various whole-grain cereals (barley, rye, and wheat), seeds, nuts, legumes, and vegetables. They are found mainly in fiber-rich food products such as cereals, vegetables, and fruits. The richest known dietary sources of enterolactone precursors are flaxseed and sesame seed. These lignans exert weak inhibitory actions on aromatase. Enterolactone levels are lower in breast cancer patients than in healthy controls, indicating its potential anticarcinogenic activity.

Coumestans

Coumestrol, a natural organic compound in the class of phytochemicals known as coumestans, is contained in a variety of plants including soybeans, clover, alfalfa sprouts, sunflower seeds, spinach, and legumes. Coumestrol inhibits the enzymatic activity of 17 β -HSD and aromatase (Sifakis et al., 2017). It also exerts antiestrogenic activity 30- to 100-fold higher than that of isoflavones by binding to ER α and ER β . Because of its estrogenic activities, coumestrol could be used as a supplement to hormone therapy and chemotherapy in breast cancer patients. Studies looking at coumestrol in animals found that it delays vaginal opening in rats. Cows that consume a significant amount of alfalfa tend to have low pregnancy rates and higher spontaneous abortion rates, resulting in a low fertility.

Mycoestrogens

Mycoestrogens are produced by fungi that contaminate cereal grains, animal feed sources, corn silage, and hay. Zearalenone is a potent estrogenic mycotoxin produced by some *Fusarium* and *Gibberella* species. Zearalenone is heat-stable and found worldwide in many cereal crops such as maize, barley, oats, wheat, rice, and sorghum (Liu et al., 2010). It is considered to be the most potent phytoestrogen in inhibiting the activity of both the reductive and oxidative activity of 17 β -HSD. Natural exposure to zearalenone in contaminated food has been implicated as a cause of female reproductive changes because of its powerful estrogenic activity. Zearalenone is metabolized by the intestinal tissue into major active metabolites: α - and β -zearalenol. The estrogenic activity of zearalenone and its metabolites is mediated by their binding affinity to estrogen receptors. Girls chronically exposed to zearalenone through the diet suffer from early puberty and several sexual disorders.

Antiestrogens as Endocrine Disrupting Chemicals

Endocrine disrupting chemicals (EDCs) are exogenous substances that can disturb the production, metabolism, transportation, action, and elimination of natural hormones due to their natural hormone-mimicking property (Casals-Casas and Desvergne, 2011; Shanle and Xu, 2011). Most EDCs exert their actions by binding to hormone receptors, including ERs, androgen receptors (AR), thyroid hormone receptors (TRs), and nonsteroidal receptors (membrane-bound receptors). An EDC may interfere with gene expression, enzyme activity, and epigenome modification (Casals-Casas and Desvergne, 2011; Patel et al., 2015; Shanle and Xu, 2011). Exposure to EDCs is frequently associated with reproductive abnormalities, metabolic disorders, cancers, and physiological problems (Casals-Casas and Desvergne, 2011; Patel et al., 2015). Of note, a variety of EDCs directly affect the ovarian function as well as steroidogenesis in females (Patel et al., 2015).

Antiestrogenic EDCs are defined as chemical compounds with an antagonistic effect on ERs or inhibitory activity on aromatase. Broadly, this definition can be extended to chemicals that inhibit the expression/activity of key enzymes that contribute to the synthesis of estradiol (E2) from cholesterol. An antiestrogenic EDC disturbs the expression/activity of aromatase or competes against endogenous estrogens in binding estrogen ERs. Antiestrogenic EDCs are classified according to their modes of actions: (1) inhibitory activity on estrogen synthesis, (2) antagonistic activity on ERs, and (3) other antiestrogenic action. Table 4 lists representative EDCs that are known to exert an antiestrogenic effect in females.

Antiestrogens With Inhibitory Activity on Estrogen Synthesis

Exposure to a variety of EDCs disrupts ovarian estrogen synthesis, thus causing ovarian dysfunction and infertility (Patel et al., 2015). Bisphenol A (BPA), methoxychlor (MXC), phthalates, and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) are representative antiestrogens acting on estrogen synthesis machinery.

BPA (bisphenol A)

BPA is used in the process of manufacturing polycarbonate plastics and epoxy resins as a plasticizer. Specifically, it is used for packaging foods and beverages, baby bottles, thermal papers (i.e., receipts), and dental sealants. In the liver, BPA is converted to 4-methyl-2,4-bis(4-hydroxyphenyl) pent-1-ene (MBP). MBP has a 1000-fold stronger binding affinity to ERs compared BPA alone. BPA exposure inhibits steroidogenesis in several animal models (Patel et al., 2015). BPA decreased estradiol synthesis in cultured ovarian cells by decreasing aromatase expression. In porcine granulosa cell culture, BPA stimulated estradiol production at a low BPA concentration (0.1 μ M) but inhibited estradiol production at higher BPA concentrations (1 and 10 μ M). In mouse antral follicle cultures, BPA acutely decreased *Cyp11a1* expression, causing a decrease of progesterone, androstenedione, testosterone, and estradiol. Also, BPA significantly decreased serum estradiol levels in rats by decreasing aromatase and *Star* expression in granulosa cells and theca interstitial cells, respectively. In humans, high BPA concentration in plasma or urine is associated with a reduced number of mature/fertilized oocytes, low response to hyperstimulation with human chorionic gonadotrophin (hCG), implantation failure, and infertility (Sifakis et al., 2017).

Table 4 List of antiestrogenic endocrine disruptors, their mode of action, and associated disorders

Chemicals	Bioactive metabolites	Usage	Mode of action	Disorders
Bisphenol A (BPA)	4-Methyl-2,4-bis(4-hydroxyphenyl)pent-1-ene (MBP)	Plasticizers	Inhibition of E2 synthesis; ER α antagonist	Endometriosis, PCOS, implantation failure, infertility
Bisphenol AF (BPAF)	BPAF diglucuronide, BPAF glucuronide (BPAF-G), BPAF glucuronide dehydrated, BPAF sulfate	Plasticizers	ER β antagonist; metabolites have no activity on ERs	Not known
Methoxychlor (MXC)	1,1,1-Trichloro-2-(4-hydroxyphenyl)-2-(4-methoxyphenyl) ethane (MOH) 2,2-Bis(<i>p</i> -hydroxyphenyl)-1,1,1-trichloroethane (HPTE)	Pesticides	E2 synthesis Inhibition of E2 synthesis; ER β antagonist; ER β hyper-methylation	Not known Impaired folliculogenesis and implantation failure in rodents
Di-(2-ethylhexyl) phthalate (DEHP)	Mono-(2ethylhexyl) phthalate (MEHP)	Plasticizers	Inhibition of E2 synthesis	Endometriosis, infertility
2,3,7,8-Tetrachlorodibenzo- <i>p</i> -dioxin (TCDD)	2,3,7-Trichloro-8-hydroxydibenzo- <i>p</i> -dioxin (OH-TriCDD); 1,3,7,8-tetrachloro-2-hydroxydibenzo- <i>p</i> -dioxin (OH-TCDD)	Byproducts	Inhibition of E2 synthesis	Endometriosis, endometriosis in TCDD-exposed rhesus monkeys

MXC (methoxychlor)

MXC is a synthetic insecticide developed as an alternative to dichlorodiphenyltrichloroethane (DDT), which was banned by the US Environmental Protection Agency in 2003 because of its acute toxicity, bioaccumulation, and endocrine disrupting properties. In the body, MXC is metabolized to 1,1,1-trichloro-2-(4-hydroxyphenyl)-2-(4-methoxyphenyl) ethane (MOH) and the 2,2-bis(*p*-hydroxyphenyl)-1,1,1-trichloroethane (HPTE) by cytochrome p450 enzymes. MXC inhibits folliculogenesis, decreases *Esr2* expression, and delays growth of antral follicles in laboratory animals. MXC and its metabolites (MOH and HPTE) decrease estrogen synthesis by inhibiting the expression of steroidogenic enzymes such as *Cyp11a1*, *Cyp17a1*, and *Cyp19a1* mRNA in laboratory animals (Patel et al., 2015; Shanle and Xu, 2011).

Phthalates

Phthalates are synthetic chemicals used as plasticizers for producing a variety of products such as medical tubing, food packaging, and infant toys. Di-(2-ethylhexyl) phthalate (DEHP), dibutyl phthalate (DBP), butyl benzyl phthalate (BBP), and diethyl phthalate (DEP) are the most prevalent phthalates in consumer products. DEHP exposure inhibits aromatase expression in antral follicles and decreases *Cyp19a1* expression and serum estradiol levels in rats. Mono-(2ethylhexyl) phthalate (MEHP), the bioactive metabolite of DEHP, inhibits aromatase expression in the cultured granulosa cells of mice, rats, and humans (Patel et al., 2015). High urine content of phthalate metabolites is associated with endometriosis incidence (Sifakis et al., 2017).

TCDD (2,3,7,8-tetrachlorodibenzo-p-dioxin)

TCDD is produced as a byproduct of solid waste burning, herbicides, pesticides, disinfectants, and paper mills. This lipophilic toxicant has a long environmental half-life and accumulates in the food chain. TCDD is found in animals and humans (in adipose tissue, serum, milk, and ovarian follicular fluid). The International Agency for Research on Cancer has classified TCDD as a carcinogen. TCDD causes reproductive dysfunctions due to its antiestrogenic actions (Patel et al., 2015). In the mouse, the nanomolar range of TCDD exposure decreases the concentration of progesterone, androstenedione, testosterone, and estradiol and inhibits the expression of steroidogenic enzymes including *Hsd17b1* and aromatase in isolated antral follicles.

EDCs on Estrogen Receptors

EDCs such as bisphenols and MXC bind to ERs and modulate ER functions by inducing conformational changes. Even though most antiestrogenic EDCs bind to ER with relatively weak affinity, the binding still induces a significant disruption in ER signaling. In addition to bisphenols and MXC, benzanthrone, disulfiram, 3,3,3',3'-tetramethyl-1,1'-spirobisindane-5, 5',6,6'-tetrol, and atrazine exhibit antiestrogenic properties with low ER α binding affinity (Akahori et al., 2008).

BPAF (bisphenol AF)

Because of the antagonistic activities of BPA against ER α , research on replacing BPA has been actively conducted. BPAF, a BPA derivative in which two methyl groups in BPA are replaced with trifluoromethyl groups is a substitute for BPA, and is manufactured to produce "BPA-free" plastic products. However, BPAF acts as an antagonist for ER β in an in vitro study (Li et al., 2012). Of note, BPAF acts as either ER agonists or antagonists depending on its concentration or tissue type. At present, various alternatives for BPA are being developed and presented, but as in the case of BPAF, their safety is not yet ensured.

MXC

As noted above, MXC decreases estradiol synthesis by inhibiting the expression of steroidogenic enzymes. MXC itself has 10,000 times lower binding affinity than E2 for ERs. A main metabolite of MXC, 2,2-Bis(*p*-hydroxyphenyl)-1,1,1-trichloroethane (HPTE), acts as an agonist for ER α and an antagonist for ER β . In peripubertal female rhesus monkeys, administration of MXC for 12 months induced precocious puberty and shortened the follicular phases. Also, HPTE inhibits follicular development in the rat ovary (Patel et al., 2015; Shanle and Xu, 2011).

Other Antiestrogenic Mechanisms of EDCs

Some EDCs disrupt the endocrine system via a nonclassical nuclear receptor signaling pathway, aryl hydrocarbon receptor (AhR), or epigenetic modification. While studies on EDCs in membrane-associated ER α or G protein-coupled receptors for estrogen (GPR30) are primarily concerned with estrogenic action, other studies showed that MXC exerts an antiestrogenic effect via epigenetic modification (Shanle and Xu, 2011). MXC induces hypermethylation in the *Esr2* gene promoter but not in the *Esr1* gene (Sifakis et al., 2017). Because DNA methylation in the CpG island of the promoter in certain genes generally causes reduction of gene expression, hypermethylation in the *Esr2* promoter by MXC may affect the receptivity for E2 in the ovary, particularly in granulosa cells.

In summary, estrogens play important roles in regulating female reproductive function and embryonic development. Some natural/synthetic antiestrogens are currently used as therapeutics for treating female reproductive disease. The most important use of antiestrogen medication is to treat breast cancer and reduce the risk of cancer remission. Research on targeting estrogen receptors as a potential anticancer drug is still ongoing. Antiestrogenic EDCs disrupt estrogen synthesis and ERs signaling, and normal

estrogen signaling is affected by unwanted exposure to antiestrogenic EDCs. The effects of antiestrogenic therapeutics and EDCs on ovaries and extra-gonadal organs that synthesize estrogen warrant further research because of their potential to drastically improve various reproductive health diseases and cancer.

Androgens in the Female Reproductive System

In females, androgens play important roles in regulating development and functions of reproductive organs as well as in maintaining muscle strength, bone density, protein balance, sexuality, and overall well-being. The main circulating androgens in women are testosterone and dihydrotestosterone (DHT). Their actions are mediated by the androgen receptor (AR), a member of the nuclear receptor superfamily. Antiandrogens are any compounds that inhibit either the production of androgens or their interaction with androgen receptor (Zhou, 2010; Walters, 2015).

In healthy women, ovaries and adrenal glands produce approximately 50% of the body's testosterone, the primary androgen, while the other half is synthesized by peripheral conversion of androgen precursors (androstenedione and DEHA), which are secreted from the adrenal glands and the ovaries (Burger, 2002). Proper androgen production is critical for both reproduction and health in females, as hyper- and hypoandrogenism lead to a variety of disorders and infertility. Hyperandrogenism caused by overproduction of androgens or decreased androgen metabolism is responsible for the most prevalent gynecological disorder, polycystic ovary syndrome (PCOS). Women with PCOS suffer from ovulatory dysfunction, infertility, and metabolic abnormalities (Goodarzi et al., 2011). Because androgens are precursors for estrogen biosynthesis, a shortage of androgens in a woman results in a hypoestrogenic condition. Hypoandrogenism is one of the main causes of osteoporosis in women.

The actions of androgens are mediated by the AR. Therefore, AR expression in a tissue is considered to be an indication that the tissue is a target of androgen action. In the ovary, the AR is expressed in the oocytes, granulosa cells, and theca cells of both preantral and antral follicles (Walters, 2015). Mice deficient in AR (ARKO) have been an essential tool for identifying the roles that androgens play in females. ARKO mice display a markedly reduced fertility accompanied by defective follicular growth, ovulation, and corpora lutea formation, indicating that androgens may play an essential role in the ovary (Cheng et al., 2013). In the uterus, AR is expressed in the glandular and luminal epithelial cells and stromal cells where androgens stimulate cell proliferation. In support, ARKO mice have thinner uteruses than their wild type littermates and also display a diminished uterine hypertrophy in response to superovulation (Cheng et al., 2013). Exposure to hydroxyflutamide, an AR antagonist, leads to suppressed decidualization and delayed initiation of implantation and fetal development in rats. Androgens also play important roles in regulating pregnancy and parturition by preventing uterine contractions during pregnancy (Burger, 2002).

In the breast, androgens suppress mammary gland growth by inhibiting the proliferation of epithelial and stromal cells where AR is expressed. Athletic women who are exposed to an excess androgen level show atrophy in their breast tissue, and dihydrotestosterone (DHT) is often used to suppress breast growth during puberty. Importantly, steroidogenic enzymes involved in androgen biosynthesis are expressed in the mammary tissue at different stages of pregnancy and lactation, indicating a *de novo* androgen synthesis in the developing mammary gland. Androgens also decrease milk production and are used to suppress unwanted lactation. Therefore, an exposure to antiandrogens will influence both development and function of reproductive organs in females.

Antiandrogens and Their Medical Uses

In women, the main androgens are testosterone and DHT, which is more potent than testosterone and is produced from testosterone by an enzyme, 5- α reductase. A variety of pathological conditions such as polycystic ovary, ovarian carcinoma, and adrenal gland carcinoma or hyperplasia lead to hyperandrogenism, a condition in which the blood androgen level is higher than the physiologically normal concentration. Women with hyperandrogenism may suffer from symptoms such as hirsutism, acne, androgenetic alopecia, menstrual abnormality, anovulation, recurrent pregnancy loss, and dyslipidemia, and they often seek medical attention for treating the symptoms (Walters et al., 2016).

Commercial Antiandrogens

Antiandrogen medications are currently used in a variety of androgen-driven pathological conditions. Antiandrogens are classified as steroidal or nonsteroidal. Nonsteroidal antiandrogens are considered to be purer than steroidal antiandrogens because they have higher specificities to their targets than steroidal ones do. Steroidal antiandrogens such as cyproterone acetate and spironolactone not only bind to AR but exhibit cross reactivity to other steroid hormone receptors. The following are antiandrogens widely used in women (Gao and Mahto, 2016).

Flutamide is a nonsteroidal antiandrogen and is used for women with PCOS as a means to control symptoms such as acne, hirsutism, and alopecia. Flutamide acts as a selective AR antagonist, displaying competitive binding affinity against testosterone and DHT.

Table 1 Natural products as antiandrogens

Product names	Sources	Treatments of	Action mechanism
White peony	Ornamental plants (<i>Paeonia lactiflora</i>)	Hirsutism	Inhibits the production of testosterone and promotes the activity of the aromatase
Licorice	Herbaceous plants (<i>Glycyrrhiza glabra</i>)	Hirsutism, hyperlipidemia atherosclerosis	Reduces free testosterone in the blood and block androgen receptors
Red reishi	Mushroom (<i>Ganoderma lucidum</i>)	Hirsutism	Inhibits 5 α reductase
Saw palmetto	Small palm tree (<i>Serenoa repens</i>)	Acne	Inhibits 5 α reductase
Spearmint	Herbaceous plants (<i>Mentha spicata</i>)	Alopecia	Inhibits 5 α reductase
		PCOS	Reduce free testosterone in blood
		Hirsutism	
		Breast cancer	
Black cohosh	Buttercup plants (<i>Actaea racemosa</i>)	Premenopausal symptoms	Inhibit breast cancer cell proliferation

Cyproterone acetate is a steroidal antiandrogen used mainly for treating acne and hirsutism and also for hormone therapy for transgender women. Cyproterone is a potent AR antagonist that competitively binds to AR against testosterone and DHT (Gao and Mahto, 2016). It also has antigonadotropic effects: it reduces the hypophyseal storage and synthesis capacity of gonadotropins in the pituitary, which suppress ovarian function and reduce serum androgen levels.

Spironolactone is a steroidal antiandrogen used for treating acne, hirsutism, and alopecia and as hormone therapy for transgender women. It reduces testosterone level by a direct inhibition of the 17 α -hydroxylase enzyme that is necessary for the biosynthesis of testosterone. Spironolactone also inhibits 5- α reductase, which is the enzyme that converts testosterone to the more potent DHT hormone. It also act as an aldosterone antagonist by inhibiting aldosterone binding to mineralocorticoid receptors in the adrenal glands, thus disrupting the sodium/potassium balance. Therefore, this drug is primarily used to treat fluid build-up due to heart failure, liver scarring, or kidney disease, and in the treatment of high blood pressure (Gao and Mahto, 2016).

Natural Products as Antiandrogens

In recent years, there has been an increasing demand for natural (or plant-derived) antiandrogens for treating hyperandrogenism in women. Natural antiandrogens are used mainly to reduce symptoms associated with polycystic ovarian syndrome (PCOS), hirsutism, and acne (Grant and Ramasamy, 2012). Natural antiandrogens are used mostly to either decrease testosterone synthesis (white peony, licorice, and spearmint) or reduce DHT level by inhibiting 5- α reductase (red reishi, saw palmetto, and *Camellia sinensis*). Table 1 lists some of the most widely used natural antiandrogens and their medical uses.

Antiandrogens as Endocrine Disrupting Chemicals

The endocrine disrupting chemicals (EDCs) are exogenous substances that can alter the normal balance of endocrine system. Some EDCs are from plants or animals, but the vast majority are synthetic chemical compounds that are produced as industrial products and released into the environment. There is considerable concern about the impact of these synthetic compounds on public health, as they are associated with a variety of pandemic health problems in men and women. In particular, exposure to EDCs during the fetal developmental period may have life-long or even transgenerational impacts, even when exposure levels are below those considered to be harmful to adults (Costa et al., 2014).

EDCs mainly interfere with the synthesis, secretion, metabolism, and transport of endogenous hormones through direct binding to specific hormone receptors. An EDC either mimics the action of a hormone or therefore exerts an “agonistic effect,” or it blocks/inhibits the hormone’s action, inducing an “antagonistic effect.” Initially, it was thought that EDCs exert their actions only by binding to nuclear hormone receptors, including estrogen receptors (ERs), AR, and thyroid hormone receptors (TRs) (Costa et al., 2014). However, recent studies show that EDCs also act through nonsteroidal receptors, transcriptional coactivators, and enzymatic pathways that are involved in steroid biosynthesis. They can also modify gene expression by causing epigenetic modifications without inducing mutation.

A number of EDCs exert antiandrogenic activity. Antiandrogenic EDCs can be classified according to their modes of actions. Some EDCs inhibit androgen synthesis, while others bind to AR. Table 2 lists representative EDCs that are known to exert antiandrogenic effect on females, and more details about different pathological effects of antiandrogens are provided in Fig. 1.

Antiandrogens With Inhibitory Activity on Testosterone Synthesis

DEHP (di-ethylhexyl phthalate)

Phthalates are a family of compounds that are used extensively in medical, automotive, and cosmetics production. There are six different types of phthalates; DEHP (di-ethylhexyl phthalate), BBP (benzyl-butyl phthalate), and DINP (diisononyl phthalate) have potent antiandrogenic properties. DEHP is the most widely used phthalate and is used mainly as a plasticizer in polyvinyl

Table 2 Synthetic chemicals as antiandrogens

<i>EDCs</i>	<i>Types</i>	<i>Active metabolite</i>	<i>Mode of action</i>
DEHP (di-ethylhexyl phthalate)	Plasticizers	MEHP	Inhibit testosterone synthesis
BBP (benzyl butyl phthalate)	Plasticizers	MBP	Inhibit testosterone synthesis
DBP (dibutyl phthalate)	Plasticizers	MBP	Inhibit testosterone synthesis
DDT (dichlorodiphenyltrichloroethane)	Organochlorine pesticide	DDE	AR antagonist
Methoxychlor	Organochlorine pesticide	HPTE	AR antagonist
Vinclozolin	Dicarboximide fungicide	M1, M2	AR antagonist
Procymidone	Dicarboximide fungicide	Not known	AR antagonist
Linuron	Urea-based herbicide	Not known	AR antagonist

**Fig. 1** Pathological effects of exposure to EDC antiandrogens in ovary, uterus and breast.

chloride (PVC) products such as plastic toys or intravenous blood bags. The main active metabolite of DEHP is mono-(2-ethylhexyl) phthalate (MEHP), which is more potent than DEHP itself and responsible for most of pathological alteration coming from DEHP exposure. Prenatal exposure to DEHP leads to reduced ovarian weight and increased uterine weight in female mice. In utero or lactational DEHP exposure alters steroidogenic gene expression in the ovary, decreases estrogen synthesis, reduces ovarian weight, and reduces ovulation. Recent studies have found harmful effects of prenatal exposure to DEHP. Prenatal DEHP exposure caused increased uterine weight and decreased anogenital distance, disrupted estrous cyclicity, and reduced fertility when the subjects were examined at their adulthood. Exposure during fetal development altered follicular recruitment and development, eventually causing premature ovarian failure.

BBP (benzyl-butyl phthalate) and DBP (dibutyl phthalate)

BBP is used mainly to make vinyl tiles, car upholstery, and adhesives, and it is often metabolized into DBP, a monobutyl phthalate (MBP). In rats, in utero exposure to BBP leads to decreased uterine and ovarian weights, decreased blood progesterone levels, and postimplantation embryonic loss. Furthermore, exposure to BBP or MBP increased the risk of postimplantation embryonic loss in rats. Fetal exposure to BBP increased embryonic demise, increased resorptions, decreased the weight of live fetuses, and increased the incidence of skeletal malformations in rats. Uterine weights and progesterone levels decreased after BBP exposure, the lower serum concentrations of progesterone explained the reduction of decidualization in pregnant rats. A study reported an increase in the number of alveolar buds and terminal ducts after in utero exposure to BBP (Harris and Sumpter, 2001).

DBP exposure via the diet from GD15-PND21 induced a trend for delayed onset of vaginal opening in Sprague–Dawley rats. DBP exposure has been shown to decrease maternal weight gain, fetal weight, and food consumption and increase the risk of losing pregnancy by in rats. Another study showed that in utero exposure to doses as low as 20 ppm DBP in the diet induced hypoplasia of the mammary glands.

Antiandrogens With Inhibitory Activity on Androgen Receptor

Vinclozolin

Vinclozolin (VZ) is a dicarboximide fungicide used mainly to treat fruits and vegetables, such as lettuce, grapes and beans. Vinclozolin or its active metabolites (M1, M2) competitively inhibits the binding of androgens to their receptors, which leads to an inhibition of androgen-dependent gene expression in mammals. Embryonic exposure to vinclozolin alters steroid receptor expression and fetal genital tubercle development, causing virilization in female mice (Kelce et al., 1997). Prenatal exposure to

Vinclozolin also reduces the anogenital distance in the female rat. In fish, exposure to 700 µg vinclozolin suppressed oocyte development. Exposure to high concentrations of vinclozolin caused abnormal ovarian pathology in rats, which exhibited an elevated incidence of ovarian lipodosis and interstitial cell hyperplasia. Furthermore, a previous study has showed the transgenerational effect of vinclozolin on DNA methylation of several imprinted genes in a mouse.

Procymidone

Procymidone is another dicarboximide fungicide similar in structure to vinclozolin and widely used to protect fruits from fungal infection. Procymidone has antiandrogenic properties, and it competitively inhibits the binding of androgens to its receptor, thereby preventing androgen function. When administered by gavage to pregnant rats (GD14–to day 3 after birth), the male pups displayed a reduced anogenital distance, nipple retention, hypospadias, and reduced accessory sex gland size. It had no effect on female pups (Ostby et al., 1999).

DDT (dichlorodiphenyltrichloroethane)

DDT is an organochlorine pesticide that has been banned in North America since 1972. The active metabolite of DDT is DDE (di-chlorodiphenyl-ethylene), which acts as androgen receptor antagonist in vivo and in vitro. DDE is ubiquitous and found in various tissues of humans throughout the world. It accumulates and persists in the environment with a half-life of more than 50 years. DDE was also found in ovarian follicular fluids and serum of women. In women undergoing in vitro fertilization, there was a correlation between high levels of DDE in follicular fluid and high levels of failed fertilization. In immature female rats, the administration of DDE resulted in a significant increase in vascular endothelial growth factor (VEGF) and insulin-like growth factor 1 in ovarian tissue, which may lead to ovarian dysfunction. In utero exposure to DDE on GD 14–18 led to reduction of AGD, hypospadias, and retained nipples in male rat offspring. A study of Alaska Native women reported that DDE concentration in serum was related to an increased risk of breast cancer. The largest study performed includes more than 2000 American women and reports that PCB and DDE concentration in serum was related to increased menstrual cycle length and irregularity. A study of Chinese textile workers indicated increased odds for spontaneous abortion with increasing total DDT and DDE serum levels (Kelce et al., 1997).

Methoxychlor

Methoxychlor is a synthetic organochlorine used as an insecticide to protect crops, livestock, and pets against insects. It was intended to replace DDT, but it has been banned because of its acute toxicity, bioaccumulation, and endocrine disruption activity. The main active metabolite of methoxychlor is HPTE (2,2-bis(p-hydroxyphenyl)-1,1,1-trichloroethane), which acts as an estrogen receptor alpha (ER α) agonist, ER β antagonist, and AR antagonist. Methoxychlor and its metabolized product HPTE are reproductive toxicants that target antral follicles of the mammalian ovary as they inhibit follicular development, reducing the number of antral follicles and increasing the preantral follicles in the rat ovary (Uzumcu et al., 2006). Oral exposure to methoxychlor in female rats for 14 days led to atresia of the ovarian follicles with pyknosis and karyorrhexis of the granulosa cells; this altered folliculogenesis and inhibited the gap junction formation between oocyte and cumulus. Administration of methoxychlor (25 and 50 mg kg⁻¹ day⁻¹) to female rhesus monkeys in the peripubertal period led to shorter follicular stages, which influence the ovarian cyclicity.

Linuron

Linuron is a urea-based herbicide that acts as a weak androgen receptor antagonist in vitro and in vivo and disrupts androgen-dependent male reproductive tract development after gestational exposure (Gray et al., 2001). When administered to pregnant rats (GD14–18; 100 mg kg⁻¹ day⁻¹), the male pups displayed a reduced anogenital distance, retention of areolas, and reduced size of androgen-dependent tissues, including seminal vesicles, ventral prostate, and epididymis.

In conclusion, it is clear that androgens play important roles in the regulation of female reproductive function and have a critical role during embryonic development and sex differentiation. It is possible that some natural antiandrogens could be used as therapeutics for modulating female and male reproductive disease. Antiandrogens have a great impact in female reproductive capacity, while many synthetic chemicals with antiandrogenic activity are still in use. Future research is needed to explore the different possible pathological hazards from these chemicals and how we can minimize the health hazards associated with them and increase the public awareness in this issue.

Estrogenic Agonist

Enrique H Luque, Mónica Muñoz-de-Toro, and Jorge G Ramos, National University of the Littoral, Santa Fe, Argentina

© 2018 Elsevier Inc. All rights reserved.

Introduction

Estrogen plays vital roles by regulating many different physiological functions in both male and female organs. Estrogen mediates its action almost entirely through its alpha and beta estrogen receptors (ER α and ER β), which further function as transcription factors. The actions of estrogens are also mediated by membrane-bound proteins such as G protein-coupled estrogen receptor (GPER), inducing a nongenomic cellular effect. Estrogenic agonists are compounds that selectively stimulate estrogen-like actions in target tissues. These compounds have different chemical structures, and may be either natural or synthetic, or can be metabolic products from a compound lacking estrogenic activity (Table 1). These compounds act or function according to the tissue in which they are.

Sources of Estrogenic Agonists

A large number of man-made chemicals are manufactured worldwide and most of them are currently released into the environment. Throughout their lives, both humans and animals are exposed to many of these chemicals, including estrogenic agonists also known as xenoestrogens or environmental estrogens, which can have a positive or negative impact on their health and lifestyle. These compounds can be found in the environment, food, cosmetics, household items, pharmaceutical products, and many other products. Some of them have been tested for hormonal activity and have been shown to have the potential to disrupt the endocrine system of many animal species, including humans. This led to the introduction of the term “endocrine disruption.” In both human and rodent models, the exposure to ubiquitous environmental estrogenic agonists during early life has been shown to disrupt the normal development of target tissues and may cause permanent adverse effects. Environmental agents that mimic or block various reproductive hormones may also have transgenerational effects, and their ubiquity has increased the concern for human and ecological health.

A well-known example of a widespread estrogen agonist is bisphenol A (BPA), one of the highest-volume chemicals produced worldwide. Most people are exposed to it daily by consuming food and beverages into which BPA has leached from polycarbonate containers, including reusable bottles and baby bottles. Although initially considered a weak environmental estrogen, BPA may be similar to 17 β -estradiol (E2) in stimulating cellular responses, especially at low but environmentally relevant doses (nM), as demonstrated by recent studies.

Agrochemical compounds such as endosulfan, glyphosate-based herbicides (GBHs), and atrazine also behave as estrogenic agonists. In adult ovariectomized rats, environmentally relevant doses of endosulfan have been found to mimic the nonuterotrophic E2 actions, strengthening the hypothesis that this pesticide is a widespread estrogen agonist. Regarding glyphosate, which is the

Table 1 Representative examples of synthetic and natural estrogenic agonists

Industrial byproducts	Polychlorinated biphenyls (PCBs) Polybrominated biphenyls (PBBs) Dioxins
Plastics and plasticizers	Bisphenol A (BPA) Phthalates
Pesticides	Methoxychlor Chlorpyrifos Dichlorodiphenyltrichloroethane and metabolites (DDT, DDE) Endosulfan (END) Atrazine (ATZ) Glyphosate-based herbicides (GBH)
Pharmaceutical agents	DES Tamoxifen Gestodene
Detergent and biodegradation products	Octyl-phenol (OP) Nonylphenol (NP)
Phytoestrogens	Genistein Coumestrol Daidzein Resveratrol Naringenin
Mycotoxins	Zearalenone
Metals	Cadmium

active ingredient of several herbicide formulations, uterotrophic assays with a GBH formulation have shown that although GBH does not alter uterine weight, it increases the luminal epithelial cell height and downregulates ER α mRNA in all GBH- and E2-treated groups. Finally, atrazine is also considered an estrogenic agonist due to its ability to induce aromatase activity and thus lead to inappropriate and excess estrogen production.

Pharmacological compounds such as tamoxifen, the first selective estrogen receptor modulator used clinically to treat breast cancer and still widely prescribed in premenopausal women, can act as both an estrogen antagonist and an estrogen agonist. Tamoxifen is an estrogen antagonist in breast and brain tissue but is an estrogen agonist in the uterus and liver. Gestodene, a potent third-generation synthetic progestin, has beneficial effects on bone, due to its biotransformation into metabolites with intrinsic estrogenic activity.

Besides the above-mentioned synthetic compounds, phytoestrogens, zearalenone (ZEN), and cadmium are examples of naturally occurring estrogen agonists. Phytoestrogens are nonsteroidal plant compounds that can behave as weak estrogen mimics or as antiestrogens. These natural plant products are grouped into several classes, including lignans, isoflavones, and coumestans. In vitro studies have shown that phytoestrogens bind both ER α and ER β . ZEN is a mycotoxin with high estrogenic activity in vitro and in vivo, which accumulates in grains mainly at preharvest but also at postharvest under poor storage conditions. Thus, ZEN is a widespread contaminant in grain-based food products. Although ZEN exhibits low acute toxicity, long-term exposure to ZEN may present a health risk due to its high estrogenic activity. Cadmium also has potent estrogen-like activity in vivo. Exposure to cadmium increases uterine wet weight, promotes growth and development of the mammary glands, and induces hormone-regulated genes in ovariectomized animals.

Tissue Targets and Mechanisms of Action of Estrogenic Agonists

Estrogen contributes to the maintenance of body homeostasis by regulating many different physiological functions. Estrogen actions in reproductive and nonreproductive tissues rely on a complex net of nuclear and extranuclear signal transduction pathways triggered by at least two ER subtypes (ER α and ER β), which belong to the nuclear receptor superfamily of ligand-inducible transcription factors. There are two major mechanisms of ER-mediated transcriptional regulation (**Fig. 1**) the so-called classical mechanism, where ERs bind directly to the promoter regions of target genes by canonical sequences like estrogen responsive elements (EREs), and the nonclassical mechanism, which involves ERs regulating gene expression by associating with other transcription factors such as c-Jun and c-Fos, which bind DNA but not by direct ER–DNA binding. Estrogenic agonists bind to ERs and interfere with their signals and intracellular functions. As aforementioned, the chemical nature of these compounds includes a variety of structures; however, a growing mass of evidence has shown that structural similarities of estrogenic agonists correlate with their estrogenic activity when the classical mechanism of action of ERs is involved. By using a 3 $\times$ perfect ERE Luc reporter (GGTCAnnnTGACC) and a pS2 imperfect ERE Luc (GGTCAnnnTGGCC), [Li et al. \(2013\)](#) demonstrated that BPA, fluorinated BPA, and HPTE (an estrogenic metabolite of the pesticide methoxychlor) strongly activate ER α ERE-mediated responses (**Fig. 1**). Other estrogenic agonists like Daidzein, Genistein, Kaempferol, and Coumestrol also induce both ER α and ER β ERE-mediated activity (**Fig. 1**). Estrogenic agonists can also activate the nonclassical ER mechanism in a manner not associated with chemical structure similarity, modulating the activity of other transcription factors such as AP-1 and Sp1. In 1995, [Webb et al.](#) first reported ER activation of the -73 collagenase AP-1 promoter. By using this promoter in different constructions in HeLa cells, these authors found ER α AP-1-mediated activation by Kaempferol, Apigenin, and Coumestrol and significant activation of the ER β AP-1 promoter by Daidzein. These data indicate that estrogen agonists activate the nonclassical ER mechanism in a manner not associated with their chemical structure.

Recent studies indicate that environmental estrogens have the ability not only to disrupt ER signaling, but also to reprogram the epigenome by altering DNA and histone methylation through rapid, nongenomic ER actions. MCF-7 breast cancer cells have been identified as targets for epigenetic reprogramming by estrogenic agonists. These observations, in addition to other published data, support the hypothesis that activation of rapid signaling by environmental estrogens can lead to epigenetic reprogramming and contribute to fertility problems and progression of some diseases.

Biomarkers

The term “biomarker” is used for a wide variety of purposes. Thus, confusion often results when biomarker development, validation, and qualification are discussed. Biomarkers are useful to bio-monitor estrogenic exposure and/or estrogenic actions. The concentrations of estrogen agonists and/or of their metabolites in samples such as urine, serum, tissue, eggs, etc. are classified as exposure biomarkers, whereas morphological, biochemical, and transcriptional (estrogen-regulated gene expression: mRNA and proteins) biomarkers that evidence biological responses are classified as Effect Biomarkers.

Representative useful biomarkers of estrogenic actions (Effect Biomarkers) used in toxicology and ecotoxicology are listed in **Table 2**.

Exposure to Estrogenic Agonists and Toxicological Effects

The developmental origins of health and disease (DOHaD) paradigm posits that, during development, there are sensitive windows in which tissue formation and function can be modified by environmental stressors (such as estrogenic agonists), which can lead to

Fig. 1 Panel (A) shows a schematic representation of the classical and nonclassical genomic mechanisms of ER-mediated transcriptional regulations of estrogens. Panel (B) shows the hypothesis that structural similarities of estrogenic agonists correlate with different mechanisms of action, using a plethora of protein intermediates that lead to a selected genomic expression (illustrated by Paola Ingaramo and Gabriela Altamirano).

Table 2 Biomarkers of estrogenic actions

Biomarkers	
Biological responses	Estrogen-sensitive genes
Uterine wet weight	Progesterone receptor (PR)

Osteoblast proliferation, differentiation, and mineralization	Lactoferrin
Reptilian sex determination	

MG, mammary gland.

increased susceptibility to adverse health outcomes across the life course. The principle for this paradigm comes from data published in the 1970s showing that daughters of mothers who took the estrogenic drug diethylstilbestrol (DES) during pregnancy experienced a greater risk of a rare vaginal cancer and other reproductive abnormalities. Since then, many studies on natural or experimental exposures to estrogenic agonists have been performed in animal models, wild animals, and humans. These studies showed that exposure to estrogenic agonists during gestation induces morphological alterations in both the stroma and epithelium of estrogen-sensitive tissues during fetal and/or neonatal life, and it has been postulated that the primary targets of estrogenic agonists are the fetal tissues that express ER. An estrogenic compound would then alter the reciprocal stroma–epithelial interactions that mediate an altered tissue differentiation and/or proliferation. In addition to this direct effect on estrogen target tissues,

estrogenic agonists may result in what has been called developmental estrogenization syndrome, indicating that many estrogenic pathways may be affected, thus resulting in altered puberty, disrupted ovarian function and infertility, endometriosis, uterine fibroids, and premature menopause.

The environmental health sciences have generated considerable attention for the possible “low-dose effects” of estrogenic agonists in mammals. The term “low-dose effects” is defined as biological changes that occur at environmentally relevant exposure levels or at doses that are lower than those reported in the United States Environmental Protection Agency standard toxicity testing guidelines. Moreover, the estrogenicity of the dose effects of estrogenic agonists varies significantly among species, and there are variations between *in vivo* and *in vitro* tests. For example, temperature sex determination in reptiles can be altered by exogenous treatment with an estrogenic substance, thus providing an important model system to determine the estrogenicity of various environmental contaminants (Table 2). However, labeling chemicals as simply estrogenic or antiestrogenic given their action in a single test species is inappropriate, because the potency of the response can also be altered given the species studied. It has been demonstrated that, in reptiles, BPA causes developmental effects similar to those observed after E2 exposure, such as sex reversal and altered gonadal histoarchitecture. The BPA dose needed to evoke an effect comparable to that of E2 in a sex reversal *in vivo* system is 100-fold larger. In contrast, data from *in vitro* studies suggest that BPA is 10,000 less potent than E2. Published results highlight the usefulness of *Caiman latirostris*, a temperature-dependent sex-determined species, as a tool to assess estrogenic activity *in vivo* and as a sentinel to monitor endocrine-disrupting chemicals in aquatic environments. Concern regarding environmental exposure to xenoestrogen and its potential impact on the development and reproduction of wildlife species is raised based on these data and upon publications showing the presence of xenoestrogens in surface waters, sediments, liquid manure samples, and sewage. Another significant issue is that most chemical exposures in the environment occur in complex combinations and mixtures.

In female mammals, estrogen agonists act as endocrine disruptors, negatively affecting several organs and systems. A detailed description of some of these adverse effects can be found below.

Brain and Hypothalamic-Pituitary Axis

Neonatal exposure to BPA alters the hypothalamic circuitry responsible for controlling estrous cyclicity and female sexual behaviors of adult rats. One of the targets of BPA action is the hypothalamic ER α gene. When female rats are neonatally exposed to BPA, this receptor is downregulated in both the medial preoptic and ventromedial nuclei, thus leading to alterations in the estrous cyclicity and inability to induce a normal E2-induced LH surge. Besides, in BPA-exposed rats, ER α protein expression is upregulated in the anteroventral periventricular nucleus and downregulated in the arcuate nucleus. Thus, neonatal BPA exposure permanently disrupts hypothalamic LHRH pre-mRNA processing in nuclei that control estrous cyclicity during adulthood. Interestingly, BPA-exposed females display significantly lower levels of proceptive sexual behavior.

Ovary and Female Reproductive Tract

Prenatal and neonatal exposure to estrogenic agonists may be responsible for disruption of follicular development. Some studies in rats have demonstrated that progesterone inhibits the assembly of primordial follicles, whereas both progesterone and estrogen reduce their initial recruitment. In mice, progesterone and estrogen prevent primordial follicle assembly, but not subsequent development. Recent observations have shown that normal folliculogenesis requires androgen receptor (AR)-mediated androgen action and that cyclin-dependent kinase inhibitor 1B, commonly known as p27kip1 or p27, suppresses primordial follicle endowment and activation and promotes follicle atresia. Exposure to DES or BPA via sc during the first 6 postnatal days disrupts follicle development in rats by reducing the primordial follicle pool by stimulating the initial recruitment, associated with an increased proliferation rate likely mediated by an estrogenic pathway. Neonatal exposure to DES or BPA also affects the ovarian follicular dynamics in lambs, showing a decline in the stock of primordial follicles with stimulation of follicular development. In these species, BPA reduces ovarian weight and increases the number of multioocyte follicles, promoting proliferation of granulosa/theca cells in antral follicles, and increasing both the number of antral atretic follicles and p27 expression. Moreover, in female lambs neonatally exposed to low doses of DES or BPA, the ovarian response to an exogenous gonadotropin stimulus (oFSH) is impaired, showing a low number of small follicles together with a lower number of atretic follicles and no increase in E2 serum levels. These alterations due to neonatal exposure to estrogen agonists may be the pathophysiological basis of the subfertility syndrome in female adulthood.

Oral exposure to BPA during rat gestation affects pup primordial follicle recruitment and increases the number of corpora lutea, indicating a larger number of ovulated oocytes, coupled with higher levels of mRNA expression of 3 β -hydroxysteroid dehydrogenase and serum progesterone. BPA-treated rat pups have lower expression of AR at different stages of the growing follicle population, evidencing an imbalance of AR expression between primordial/primary follicles, with higher mRNA-follicle-stimulating hormone receptor expression. These results add to the growing evidence that folliculogenesis and steroidogenesis are targets of BPA within the ovary.

Uterus and Implantation Process

The uterus is also a target for estrogenic agonists. Successful implantation is the result of complex molecular interactions between the hormonally primed uterus and a mature blastocyst. This carefully synchronized interplay of hormonal signals and feedback

loops is potentially vulnerable to chemicals such as estrogenic agonists that may disrupt endocrine signaling. Morphoregulator genes like members of the *Hox* gene family regulate uterine development and may be associated with endocrine-related processes such as endometrial proliferation and differentiation in the uterus. Neonatal exposure to estrogen agonists could affect the signaling events governed by *Hox* genes, altering the developmental trajectory of the uterus with lasting consequences during the preimplantation period. Neonatal exposure to xenoestrogens alters *Hoxa10* and *Hoxa11* uterine expression shortly after treatment as well as in the adult. Xenoestrogen exposure also affects the steroid-hormone responsiveness of the preimplantation uterus. These molecular alterations could explain, at least in part, the adverse effects of xenoestrogens on uterine implantation. Exposure to estrogenic agonists such as BPA, DES, endosulfan or glyphosate could contribute to the impaired female fertility noted over the past decades.

Perinatal (gestation + lactation) exposure to DES and estrogen replacement therapy induce cystic glands, glands with daughter glands, conglomerate of glands, and a decrease in progesterone receptor (PR) in the subepithelial stroma of the rat uterus. These long-lasting effects of perinatal exposure to DES include the induction of abnormalities in uterine tissues of aged female rats and an altered response of the adult uterus to E2.

Studies on the effects of neonatal exposure to BPA on the uterine response to estrogen replacement therapy in aged rats have shown an increased density of glands with squamous metaplasia and glands with daughter glands. Rats exposed to BPA and then treated with estrogen show lower *Wnt7a* (a member of the *Wnt* gene family) expression in squamous metaplasia. BPA-treated rats also show lower expression of ER α and its 5'-untranslated exons ESR1-O and ESR1-OT in the uterus. Moreover, BPA modifies the expression of uterine ER α coactivator proteins and epigenetic regulatory enzymes. Thus, perinatal estrogenic agonists-exposed rats show different glandular abnormalities associated with deregulated expression of E2-target genes.

As aforementioned, endosulfan behaves as an estrogenic agonists, and neonatal exposure to low doses of endosulfan alters the expression of proteins regulating uterine development and differentiation (i.e., *Hoxa 10* and α -smooth muscle actin expression), namely a dysregulation of steroid receptors. An aberrant ER α uterine expression is associated with a decrease in the DNA methylation status during the preimplantation period. Endosulfan increases the expression of ER α and its transcript variants ER α -OS, ER α -O, ER α -OT, and ER α -E1. Moreover, decreased DNA methylation levels have been detected in some ER α regulatory regions, suggesting an epigenetic upregulation of its transcriptions. ER α overexpression has been associated with an induction of its downstream genes, *MUC-1* and *IGF-1*, suggesting that endosulfan might alter the uterine estrogenic pathway, compromising uterine receptivity. These alterations could account, at least in part, for endosulfan-induced implantation failures.

Neonatal exposure to a GBH affects uterine morphology, proliferation and expression of proteins that regulate uterine organogenetic differentiation in rats. GBH-exposed uteri show morphological changes, characterized by an increase in the incidence of luminal epithelial hyperplasia and an increase in the stromal and myometrial thickness. GBH treatment increases cell proliferation and alters the expression of proteins involved in uterine organogenetic differentiation (ER α , PR, *Hoxa10*, *Wnt7a*). All these changes may alter the functional differentiation of the uterus, affecting female fertility and/or promoting the development of neoplasias. Neonatal exposure to a GBH also alters the reproductive performance and the molecular mechanisms involved in the decidualization process in adult rats. GBH-exposed rats show an increased number of resorption sites, associated with an altered decidualization response, as well as morphological and molecular changes at the implantation sites, associated with decreased expression of ER α and PR, a downregulation of *COUP-TFII* (*Nr2f2*) and *Bmp2* mRNA and increased expression of *HOXA10* and increased cellular proliferation. These alterations in endometrial decidualization might be the mechanism of GBH-induced postimplantation embryo loss.

The female reproductive tract disorders caused by exposure to endocrine disruptors have not been totally clarified. Different mechanisms would be involved in the effects on the uterus during implantation and development depending on the estrogenic agonist compound (BPA, DES, endosulfan, or glyphosate) and the dose administered. BPA may alter overall female reproductive capacity by affecting the morphology and function of the female reproductive system, including the ovary, and may be associated with infertility in women.

Mammary Gland and Lactation

Exposure to estrogens throughout a woman's life, including the period of intrauterine development, is a risk factor for the development of breast cancer. The increased incidence of breast cancer noted during the last years may have been caused, in part, by exposure of women to estrogenic agonists. The mammary glands (MG) of BPA-exposed rodents show differences in the rate of ductal migration into the stroma during initial development and a significant increase in the percentage of ducts, terminal ducts, terminal end buds, and alveolar buds at adult age. The altered cellular proliferation and histoarchitecture, coupled with an increased presence of secretory product within alveoli, resemble those of early pregnancy, suggesting disruption of the hypothalamic-pituitary-ovarian axis and/or misexpression of developmental genes. The altered relationship in cellular proliferation between the epithelium and stroma and the increase in terminal ducts and terminal end buds are striking, because these changes are associated with carcinogenesis in both rodents and humans.

Prenatal exposure to BPA alters the endocrine environment of the MG and its angiogenic process, associated with higher expression of vascular endothelial growth factor and increased vascular areas. The increased angiogenesis and altered steroid hormone signals could explain the higher frequency of preneoplastic lesions later in life. Of special concern is the increased terminal end bud density at puberty and the increased number of terminal ends at adulthood, as these two structures are the sites at which

cancer arises in humans and rodents. Besides affecting the female MG, BPA, and endosulfan modify the development of the male rat MG by inducing low expression of AR.

Xenoestrogen-exposed rats also show changes in milk protein and fatty acid synthesis and secretion during lactation. Modifications in female MG morphology and differentiation due to estrogenic agonists exposure could alter the quality and quantity of milk produced by the exposed individuals. Thus, perinatal exposure to environmentally relevant xenoestrogen doses results in persistent alterations in MG morphogenesis and functional activity.

Organochlorine compounds (OCCs), such as pesticides and polychlorinated biphenyls (PCBs), are persistent lipophilic chemicals, some of which have been identified as endocrine disruptors, mainly with estrogen-like effects. Some areas of Argentina characterized by intensive farming and agricultural activities and industrial development present a high incidence of environmental and dietary exposure to OCCs. Both the frequency of occurrence and levels of OCC residues in breast adipose tissue are high. The diet is a relevant source of OCC exposure, with consumption of animal fat and freshwater fish playing a significant role. Bioaccumulation is evidenced by the significant positive association between organochlorine levels and body mass index and the age of the patient. The amount and quality of OCC residues in adipose tissue adjacent to breast carcinoma affect the biological behavior of the tumor. All the ER α -positive breast carcinomas from postmenopausal women exhibit high proliferation when OCC levels in the surrounding adipose tissue reach high levels, supporting the hypothesis that OCC residues in adipose tissue adjacent to breast carcinoma generate an estrogenic microenvironment that influences the biological behavior of the tumor through ER α activation and ER α -dependent proliferation.

Estrogenic Agonists as Obesogens

The prevalence of obesity, metabolic syndrome, and type-2 diabetes has dramatically increased worldwide over the last few decades. Although genetic predisposition and lifestyle factors like decreased physical activity and energy-dense diet are well-known factors in the pathophysiology of these conditions, accumulating evidence suggests that the increase in estrogenic agonists in the environment also explains a substantial part of the incidence of the mentioned diseases. "Obesogens" are defined as chemicals that promote obesity by increasing the number of fat cells and/or the storage of fat in existing adipocytes. Obesogens can also promote obesity indirectly by shifting the energy balance to favor storage of calories, altering the basal metabolic rate, changing the gut microbiota to promote food storage, and disturbing hormonal control of appetite and satiety. New obesogens, including chemicals that cause or lead to diabetes as well as to altered lipid metabolism and fatty liver, are being identified at an increasing rate.

Epidemiological evidence and in vivo experimental data suggest an association between prenatal exposure to BPA and increased body fat at school age, induction of insulin resistance, and/or disruption of pancreatic beta cell function. Thus, it may be inferred that BPA exposure may be involved in some metabolic disorders associated with obesity.

Perinatal exposure to BPA impairs glucose homeostasis, induces obesity, and increases food intake in adult rodents, altering hypothalamic feeding circuitry. These effects could be mediated by the downregulation of ER α through a reduction of its promoter activity. BPA partially mimics the mechanisms of obesity produced by the feeding with a high-fat diet, and the combination of exposure to BPA and a high-fat diet results in an exacerbation of the individual effects.

Exposure to other estrogen agonists such as dichlorodiphenyldichloroethylene, hexachlorobenzene, or PCBs has been also linked to obesity later in life.

Conclusions

Estrogenic agonists are compounds that selectively stimulate estrogen-like actions in target tissues. These compounds have different chemical structures, and can be natural, synthetic, or metabolic products from a compound lacking estrogenic activity. As representative examples of estrogenic agonists, we can mention industrial byproducts, plastics and plasticizers, pesticides, pharmaceutical agents, detergents and biodegradation products, phytoestrogens, mycotoxins, and metals. All these compounds are present in the environment and it has been demonstrated that domestic animals, wildlife animals, and humans are contaminated with them. It is important to mention that neither animals nor humans are prepared to metabolize and detox these man-made chemicals, a fact that increases their body burden.

In environmental health sciences, the principle for the DOHaD paradigm assumes that there are developmental sensitive windows in which environmental estrogenic agonists can modify tissue differentiation and function, thus leading to increased susceptibility to adverse health outcomes during the individual's life. A limited number of studies in humans have related the exposure to estrogenic agonists to a health outcome. These include some endpoints and a variety of chemicals related to adverse effects on female reproductive organs and fertility. A better understanding of this research area will enable recommendations to prevent prenatal/in utero adverse exposures related to later adverse health outcomes.

Diethylstilbestrol (DES)

Sarah Bjorkman and Hugh S Taylor, Yale School of Medicine, New Haven, CT, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Diethylstilbestrol (DES) is a synthetic estrogen analogue prescribed to pregnant women during the mid 1900s with the belief that it helped to reduce the risk of miscarriage and preterm delivery (Smith and Gabbe, 1999). This thought continued despite a large placebo-controlled, double-blind study in 1951 showing that DES had no such positive benefit (Dieckmann et al., 1999). The continued prescription of DES without evidence of its efficacy, combined with a large production base and vast potential patient population, led millions of women and developing infants in the US and around the world to be exposed to DES between 1940 and 1971 (Goodman et al., 2011). This widespread exposure has, unfortunately, not been without consequence. There are now well-established adverse effects of direct, and most notably, in utero exposure to DES, including vaginal and clear cell adenocarcinoma, (Herbst et al., 1971; Hill, 1973) structural and functional reproductive tract anomalies (Bibbo et al., 1977; Kaufman et al., 2000; Senekjian et al., 1988), many pregnancy complications (Kaufman et al., 2000, 1980; Barnes et al., 1980; Goldberg and Falcone, 1999), and even deleterious psychosexual effects (Guterman et al., 1986; Katz et al., 1987).

History, Development, and Initial Use

DES was first synthesized in 1938 by Leon Golberg and Sir Robert Robinson at the University of Oxford's Courtauld Institute of Biochemistry–Dyson Perrins Laboratory (Dodds et al., 1938). Funding for the research leading to the initial synthesis of DES was provided by the UK Medical Research Council, which prohibited the patenting of medications discovered using public funds. This lack of patent restriction subsequently led DES to be produced by over 200 different makers world-wide. This resulted in a rapid distribution and vast area of influence (Meyers, 1983). Between 1940 and 1978, it is estimated that 5–10 million pregnant women, and children born to these women, were exposed to DES in the United States, with millions more exposures across the globe (Giusti et al., 1995).

Developed as an estrogen analogue, DES was initially marketed and utilized for the relief of a wide variety of symptoms related to estrogen-deficient states, with initial FDA approved indications for gonorrheal vaginitis, atrophic vaginitis, menopausal symptoms, and postpartum lactation suppression to prevent breast engorgement (Goodman et al., 2011; Meyers, 1983). In the early 1940s, placental hormones were believed to play a positive role in the continuation of pregnancy, and research at the time suggested beneficial results of using DES as the estrogen of choice in preventing miscarriage (Bamigboye and Morris, 2003). This presumptive data lead to the off-label use of DES for the prevention of miscarriage beginning in the early 1940's, with official FDA approval for this indication beginning in 1947. An inadequately controlled observational study by O. Watkins Smith and her husband in 1948 claimed to further support the use of DES in prevention of early abortion and later-pregnancy complications (Smith and Gabbe, 1999). However, in 1953, W. J. Dieckmann presented his placebo-controlled, double-blind study to the American Gynecological Society showing that DES did not reduce the incidence of abortion, prematurity, or postmaturity. His work also refuted the Smith's findings that DES decreased the rates of toxemias of pregnancy and perinatal mortality (Dieckmann et al., 1999). Despite Dieckmann's work, DES continued to be prescribed to pregnant mothers in the US until 1971.

In 1971, a landmark article by Herbst published in the New England Journal of Medicine reported that in utero exposure to DES was associated with the development of vaginal clear cell adenocarcinoma in adolescent females (Herbst et al., 1971). This finding was followed by a nationwide notification of physicians by the FDA that DES should not be prescribed to pregnant women (Selected Item from the FDA Drug Bulletin—November 1971, 1972). In 1975, further investigation into the scope and severity of the effect from DES exposure was undertaken by the National Cancer Institute. The institute's initiation of the DES-Adenosis Project thus began the illumination of many teratogenic and carcinogenic effects from prenatal exposure to DES (Hoover et al., 2011).

After 1971, DES use continued for medical indications outside of pregnancy. Its use as a post-coital contraceptive slowed in 1975 when the FDA mandated that packaging required the label, "This drug product should not be used as a post-coital contraceptive" (FDA, 1975). Advanced breast cancer in postmenopausal women was treated primarily with DES until the approval of Tamoxifen in 1977 (Ingle et al., 1981). In men, DES was used as the first-line treatment for advanced prostate cancer from 1941 through 1985, until Leuprolide was found to have similar efficacy (The Leuprolide Study Group, 1984). The FDA finally withdrew approval for DES in September of 2000 (FR Doc No: 00-23477, 2000).

Outside of direct human exposure, DES was also used as an additive to livestock feed in the 1960s. Given an incidence of similar unique diagnoses occurring in women who had not been exposed to DES directly or in utero, there is some conjecture that the mothers of young women who developed CCA may have been exposed to DES through dietary sources (Goodman et al., 2011) (Fig. 1).

Fig. 1 Chemical structures of Estradiol and Diethylstilbestrol.

Mechanism of Action

As an Estrogen Receptor Agonist

DES is a nonsteroidal open-ring analogue of estradiol, and functions as a full agonist of nuclear estrogen receptors (ERs). ERs are expressed in two separate classes, ER α and ER β . In vivo activation of ERs is accomplished by estrogens, with the most abundant being estradiol (17 β -estradiol) (Dahlman-Wright et al., 2006). In discussing the effects of DES, it is important to note the expression patterns of ER α and ER β . ER α is expressed in the uterine endometrium, ovarian stromal cells, the hypothalamus, and breast cancer cells (Yaghmaie et al., 2005). It is also expressed in the epithelium of the efferent ducts in males (Hess, 2003). ER β is expressed in the kidneys, brain, bone, heart, lungs, intestinal mucosa, prostate, ovarian granulosa cells, and endothelial cells (Babiker et al., 2002).

Molecular dimensions of DES, as determined by x-ray crystallography, are nearly identical to those of estradiol, with notable equal distances between the hydroxyl groups at either end of the molecules (Ravina, 2011). The widespread effect of DES is secondary to the nearly ubiquitous expression of ERs throughout the female and male bodies, and further compounded by DES's elevated binding affinity over that of estradiol. When compared to estradiol, DES has a binding affinity 4.68 times greater at ER α and 2.95 times greater at ER β (Kuiper et al., 1997). Without competition, DES preferentially binds ER β with EC50 of 0.06 nM compared to an EC50 of 0.18 nM required at ER α (Coss et al., 2012).

As a Modulator of Fetal Development

The most notorious effect of DES use occurs not because of its classic action as an estrogen receptor agonist, but rather from its ability to cross the placenta and cause in utero effects on fetal development. DES affects fetal development by acting as an endocrine disruptor (Bromer et al., 2009; Hill et al., 1980; Akbas et al., 2004). The developing müllerian system, which eventually forms the female reproductive tract, is coded for by the homeobox gene orthologs HOXA9, HOXA10, HOXA11, and HOXA13 (Taylor et al., 1997). Normally, HOXA9 develops the oviduct at the rostral end of the human paramesonephric duct, HOXA10 is associated with the rudimentary uterus (uterine anlage), HOXA11 associated with both uterine and cervical anlagen, and HOXA13 is expressed in the caudally developing vagina (Taylor, 2008). In the short-term, use of DES directly stimulates HOXA10, causing hypermethylation of this HOXA10 gene during what is thought to be a critical window of development. This leads to long-term epigenetic change (Taylor, 2008; Titus-Ernstoff et al., 2008). Through teratogenic effect, hypermethylation subsequently functions as a mechanism of change to developmental programming where HOXA10 is expressed in both uterine and cervical segments of the developing paramesonephric duct, and HOXA11 is confined to the cervical anlage (Bromer et al., 2009; Daftary and Taylor, 2006; Sassoon, 1999). Common defects that appear as consequence of these teratogenic effects include structural, functional, and cellular changes throughout the female and male reproductive tracts which are detailed later in this article (Fig. 2).

As a Carcinogen

In addition to teratogenic changes in fetal development, DES has been discovered to play a significant role as a carcinogen. Its effect on HOX and Wnt gene families is believed to be responsible for preventing the stratification of vaginal epithelium and resorption of vaginal glands, leading to vaginal adenosis and loss of the uterotubal junction (Block et al., 2000; Ma, 2009; Laronda et al., 2012). This change is thought to play a role in estrogen's alteration of stromal epithelium leading to carcinogenic change (Block et al., 2000; Ma, 2009; Laronda et al., 2012). During the postmenarcheal adolescent period, hormonal changes trigger vaginal adenosis whereby the glandular epithelium is exposed to the environment. Glandular cells comprising the adenosis are normally protected inside of the uterus and cervix, however after DES exposure are located in the vagina, which is normally protected by a squamous epithelium. The glandular cells of the adenosis are now inappropriately "in harm's way" exposed to carcinogens in the environment and leading to the well-known peak incidence of clear cell adenocarcinoma during the teenage years of women exposed to DES during their fetal development (Guzman and Zambrano, 2007). Exposure to DES during in utero development also increases the risk for other vaginal and cervical carcinogenic change, including cervical intraepithelial neoplasia (Hoover et al., 2011). The lasting carcinogenic effects and epigenetic changes of DES are now known to be heritable in animal models, and are associated with increased rates of malignant and benign uterine and ovarian tumors in the female offspring of females who were exposed to DES during their in utero fetal development (Titus-Ernstoff et al., 2006, 2008; Newbold et al., 1998, 2006; Holliday, 1998; Walker, 1984; Turusov et al., 1992).

Fig. 2 Schematic representation of the spatial domains of expression of the homeobox gene orthologs HOXA9, HOXA10, HOXA11, and HOXA13 in the developing human paramesonephric duct. In keeping with the property of collinearity, the most 3' ortholog HOXA9 is expressed rostrally in the developing oviduct, whereas the most 5' ortholog HOXA13 is expressed in the developing vagina. The ortholog HOXA10 is associated with the uterine anlage, and HOXA11 is expressed in both the uterine and cervical anlagen. In utero exposure to the endocrine disruptor DES results in a posterior shift in the spatial domains of expression of these HOX orthologs. Consequently, in DES-exposed animals, HOXA9 is expressed in the uterine anlage, HOXA10 is expressed in the caudal uterine and cervical anlagen, and HOXA11 is confined to the developing cervix. The spatial domain of expression of HOXA13 remains unaffected. A shift in the spatial domains of expression of the various HOX genes may be one mechanism for DES-related teratogenicity. As taken from *Endocrine Regulation of Hox Genes* Daftary, G. S., Taylor, H. S. (2006). *Endocrine regulation of HOX genes. Endocrine Reviews*. 27, 331–355.

Deleterious Effects

DES gained its infamy from the unintended negative effects caused to women who were exposed to the medication during pregnancy (DES mothers), and, to a much greater extent, on those who were exposed to DES while developing in utero (DES daughters and DES sons). The total number of these DES mothers, daughters, and sons in the US is estimated between 5 and 10 million persons, with millions more exposed around the world (Giusti et al., 1995). As research continues on the lasting epigenetic changes caused by DES, deleterious effects are also being found in generations removed from direct exposure to DES (DES granddaughters, etc) (Titus-Ernstoff et al., 2008).

Outcomes From Direct Exposure (DES Mothers)

Women directly exposed to DES have been shown to have a moderately increased risk of breast cancer, with a reported relative risk of 1.27–1.4 as compared unexposed controls (Titus-Ernstoff et al., 2001; Laitman, 2002). There is also an increased risk of fatal breast cancers (Calle et al., 1996), and a slight but significant increase in all-cause mortality in women exposed to DES (Titus-Ernstoff et al., 2006). No evidence exists that DES mothers are at a higher risk for any type of cancer other than breast cancer, including endometrial or ovarian cancers (Giusti et al., 1995; Titus-Ernstoff et al., 2001; Troisi et al., 2007).

Outcomes From In Utero Exposure in Women (DES Daughters)

Women exposed to DES while developing in utero (DES daughters) are known to have a significant increased risk of developing various types of cancers, malformations of the female reproductive tract, pregnancy problems, and many other adverse effects.

Clear cell adenocarcinoma and precursors to reproductive tract cancer

The most prominent and first discovered negative effect of DES was the dramatic increase in the risk of clear cell adenocarcinoma (CCA) in adolescent females who had been exposed prenatally (Herbst et al., 1971). This causality was first discovered in the late 1960s after the appearance of a cluster of cases in one institution where the affected young women had prenatal exposure to DES (Herbst and Scully, 1970). Further investigation has shown a 40-fold increase in the risk of CCA of the vagina and cervix in DES daughters (Troisi et al., 2007; Swan, 2000). The incidence of CCA has been reported as 1 per 1000 by age 34 (Melnick et al., 1987), and 1.6 per 1000 by age 39 (Troisi et al., 2007). Notably, the median age of CCA diagnosis in DES daughters is in the late second decade, as compared to the previously rare occurrence of CCA seen almost exclusively in postmenopausal women (Goodman et al., 2011; Herbst and Anderson, 1990). The increased risk of CCA in DES daughters has been associated with several risk factors including maternal history of miscarriage, exposure to DES early in gestation, birth during autumn, and prematurity (Herbst and Anderson, 1990). There is no evidence of an association between pregnancy and adverse tumor characteristics, or worse prognosis (Herbst and Anderson, 1990). DES daughters are at increased risk of developing other carcinogenic changes in the reproductive tract. They are nearly 2.3 times more likely to develop cancer precursor cells (cervical intraepithelial neoplasia Grade II or worse) than nonexposed women (Hoover et al., 2011). Nearly 95% of DES daughters will have abnormal columnar epithelium

of the cervix and/or upper vagina, and 75% exposed prior to the 9th week of gestation will have vaginal adenosis (Barclay, 1979; Herbst et al., 1972).

Breast cancer

Repeated evidence in the US shows that DES daughters are at an increased risk of developing breast cancer (Hatch et al., 1998), with 2% of DES daughters developing breast cancer attributable to their exposure (Hoover et al., 2011). This increased risk is demonstrated in women after 40 years of age, with DES daughters approximately twice as likely to develop breast cancer as unexposed women with similar risk factors after this age (Troisi et al., 2007; Palmer et al., 2002, 2006). The mechanism for an increased risk of breast cancer after DES exposure is unknown, but speculated that changes in breast tissue may be mediated by the proliferative effects of estrogen (Larson et al., 2006). Epigenetic programming of genes that increase risk of breast cancer has also been described (Doherty et al., 2010).

Reproductive tract anomalies and issues with fertility

DES daughters frequently have abnormalities of the reproductive tract that can predispose to problems with reproduction (Kinch, 1982). These abnormalities can include cervical hoods or ridges, small t-shaped uteri, other abnormalities of the uterine cavity, uterine leiomyomas, and abnormalities of the fallopian tubes (Barclay, 1979; Kinch, 1982; Kaufman et al., 1977; DeCherney et al., 1981; Newbold, 2004; Baird and diethylstilbestrol, 2005). Primary cervical abnormalities include hypoplasia and shortened cervical structure (Milhan, 1992). In relation to the structural abnormalities of the uterus and fallopian tubes, DES daughters are more than twice as likely to have primary infertility than nonexposed women (Milhan, 1992; Palmer et al., 2001). A higher percentage of DES daughters than non-exposed women report trying to become pregnant without success for at least 12 months, and are also more likely to never have become pregnant (Palmer et al., 2001).

Complications in pregnancy

In addition to having difficulty becoming pregnant, DES daughters have significantly increased risk of pregnancy complications. Major complications include preterm delivery, spontaneous abortions, second trimester losses, stillbirth, neonatal death, ectopic pregnancy, and preeclampsia (Goodman et al., 2011; Kaufman et al., 2000; Kinch, 1982). Many of these complications are believed to be related to structural abnormalities in the uterus that make it difficult for the uterus to accommodate for a growing fetus (Goodman et al., 2011). In 2011, a paper published in the New England Journal of Medicine reported excess risk of these complications in DES daughters as follows: preterm delivery 35.4%, spontaneous abortions 38.6%, second trimester losses 14.7%, stillbirth 6.3%, neonatal death 7.2%, ectopic pregnancy 11.7%, and preeclampsia 13.7% (Goodman et al., 2011).

Other deleterious effects

DES daughters are reported to have more problematic sexual lives, to seem more depressive, to be more poorly adjusted to life, and to have other negative psychosexual effects. These effects are postulated to be secondary to a psychological vulnerability related to long-term stress from the obstetric and gynecologic problems they face as a result of their DES exposure (Guterman et al., 1986; Katz et al., 1987; Giusti et al., 1995). Additionally, DES daughters are 50% more likely to experience early menopause (menopause prior to age 45) than unexposed women, giving them an incidence rate of nearly 3% (Hoover et al., 2011; Hatch et al., 2006). DES daughters have also been reported to have immune system disorders (NIH DES Research Update, 1999), but there has been no difference found in the rates of rheumatologic disorders such as lupus, rheumatoid arthritis, optic neuritis, and idiopathic thrombocytopenic purpura (Strohsnitter et al., 2010).

Unique medical management

Given the many known adverse effects of in utero exposure to DES, DES daughters should have a complete pelvic examination yearly beginning at menarche or by age 14, with an interval for follow-up determined on an individual basis (Barclay, 1979; Anon, 1983).

Outcomes From In Utero Exposure in Men (DES Sons)

In addition to the major effect of in utero DES exposure on the female reproductive tract, significant consequences have also been found in males who were exposed to this substance during their fetal development. These deleterious effects seen at increased rates in DES sons can be structural, functional, or cellular abnormalities, and include hypospadias, microphallus, retained testes, testicular hypoplasia, cryptorchidism, epididymal cysts, and testicular inflammation (Giusti et al., 1995; Guzman and Zambrano, 2007; Kinch, 1982; NIH DES Research Update, 1999). Relative risks for these abnormalities are as follows: cryptorchidism 1.9%, epididymal cyst 2.5%, and testicular inflammation 2.4%. These relative risks are increased when examining only DES sons who were exposed prior to the 11th week of gestation to 2.9%, 3.5%, and 3.0% respectively (Palmer et al., 2009). Notably, there is no evidence to suggest a statistically significant difference in rates of varicocele, urethral stenosis, benign prostatic hypertrophy, or inflammation of the prostate between DES sons and unexposed men (Palmer et al., 2009). DES sons have been found to not have an increased rate of subfertility or infertility (Wilcox et al., 1995). There is currently no significant evidence to show increased risk of testicular cancer in DES sons, despite suspicion that a statistically significant difference may appear as this population continues to be studied (Strohsnitter et al., 2001). There is also no increase in the incidence of prostate cancer in DES sons to

date (Newbold, 2004). As is the case in their female counterparts, DES sons have been shown to have an increased rate of psychosexual effects (Giusti et al., 1995).

Lasting Epigenetic Change in Future Generations (DES Granddaughters and Grandsons)

Research continues to follow the children of DES daughters, as repeated animal models have shown multigenerational effects of in utero DES exposure (Titus-Ernstoff et al., 2008; Turusov et al., 1992; Newbold et al., 1998). These findings have given concern that similar events may be seen in future human generations. To date, however, limited such evidence has been found (Titus-Ernstoff et al., 2008). Some recent studies have shown that DES granddaughters and DES grandsons may have slightly increased risks of cancer and birth defects, but these have all been limited by a small sample size (Titus-Ernstoff et al., 2008, 2010; Klip et al., 2002). Evidence that DES granddaughters have a higher incidence of later menarche and menstrual irregularities has been found, but also lacked statistical significance given the small number of events (Titus-Ernstoff et al., 2006).

Glossary

DNA methylation An epigenetic process in which a methyl group attaches to a cytosine molecule that is next to a guanine on the DNA strand.

Epigenetics Molecular factors and processes around DNA that regulate genome activity independent of DNA sequence, and which are mitotically stable.

Polycystic ovarian syndrome (PCOS) An individual having Oligo/anovulation, hyperandrogenism, or polycystic ovaries on an ultrasound. In humans, PCOS is characterized as an individual having two of the three above conditions.

Primary ovary insufficiency (POI) A condition characterized by marked follicular loss within the ovaries and menopause before the age of 40 in humans.

Transgenerational epigenetic inheritance Germline (sperm or egg) transmission of epigenetic information between generations in the absence of any continued direct exposures or genetic manipulations.

Introduction

Epigenetic mechanisms can mediate changes in an organism's phenotype or gene expression patterns that occur in response to environmental factors. Epigenetic processes include DNA methylation, modifications to histone proteins, expression of non-coding RNA, and changes to chromatin structure. Ancestral exposure to a variety of environmental factors, such as toxicants or abnormal nutrition, has been shown to promote changes in transgenerational gene expression and disease frequency (Skinner, 2014). This concept is known as multigenerational or transgenerational epigenetic inheritance. Transgenerational phenomena are inherited changes that do not involve any form of continued direct environmental factor exposure, while multigenerational inheritance involves direct exposures to the animal, developing embryo, or developing gametes within a developing embryo. Transgenerational epigenetic inheritance requires that epigenetic information or epigenetic changes are present in germ cells (i.e., sperm or eggs), as it is through germ cells that inheritance occurs.

There are some periods of an organism's development that are sensitive to environmental impacts, during which exposure to environmental factors can change the epigenetic landscape around an organism's DNA. In mammals one such sensitive window is during the period of gonadal sex determination, at which time extensive epigenetic modifications are already occurring in the developing germ cells (Messerschmidt et al., 2014). Toxicants administered to a pregnant F0 generation female at this time directly expose the developing pups (F1 generation) to the toxicant, as well as exposing the developing gametes within those pups, which will become the F2 generation. Thus, a transgenerational effect can only be seen in the F3 generation animals (great-grand-offspring) and beyond because those animals would not be directly exposed to any toxicants. In contrast, in the event an adult male or nonpregnant female is exposed, the F0 generation adult and the germ cells that will generate the F1 generation are directly exposed, and examination of the F2 generation (grand-offspring) is required to demonstrate a transgenerational phenomenon (Skinner, 2008, Fig. 1).

Ovarian diseases affect many individuals throughout the world. The two most common types of ovarian diseases are polycystic ovarian syndrome (PCOS) and primary ovarian insufficiency (POI). Polycystic ovarian syndrome affects 12%–21% of women of reproductive age (March et al., 2010). PCOS in humans is characterized by a combination of different ovarian abnormalities including oligo/anovulation, hyperandrogenism, and polycystic ovaries on an ultrasound (Boyle and Teede, 2012). Primary ovary insufficiency is a condition characterized by oocyte loss within the ovaries and menopause before the age of 40 in humans (Laven, 2016).

Transgenerational epigenetic effects caused by different factors, such as environmental pollutants, can be evaluated both in terms of molecular epigenetic changes induced within the cells of descendants, and in characterizing observable phenotypic changes in descendants, such as increases in disease frequencies.

Transgenerational Reproductive Effects

Several environmental toxicants have been studied in model animal species for the potential transgenerational epigenetic effects they may have on female reproduction.

Fig. 1 Rat lineage example showing an F0 generation pregnant animal exposed to a toxicant, and illustrating that the multigenerational F1 and F2 generations were also directly exposed, while the transgenerational F3 generation had no direct exposure. Modified from Skinner, M.K., 2008. What is an epigenetic transgenerational phenotype? F3 or F2. *Reproductive Toxicology*, 25, 2–6.

Vinclozolin is a known antiandrogenic fungicide that is commonly used on fruits and vegetables, specifically wine grapes in the United States (Anway and Skinner, 2006). Following exposure of F0 generation pregnant rats to vinclozolin, the directly exposed F1 generation females at 1 year of age showed a significant increase in small ovarian cysts compared to controls. This resembles PCOS in humans. These F1 generation ovaries also had a significant decrease in primordial and developing follicles, reflecting a reduction in the total number of oocytes in the ovary. Such decreases in the primordial follicle pool size are similar to what is seen in POI in humans and may lead to lower fertility. In the non-exposed F3 generation of vinclozolin lineage animals, the ovaries showed an increased incidence of both small and large ovarian cysts, as well as a significant decrease in oocyte numbers (Nilsson et al., 2012). This F3 generation phenotype indicates epigenetic transgenerational inheritance of ovarian disease. Ancestral exposure to vinclozolin in rats has also resulted in an increase in uterine bleeding events late in pregnancy in the F1–F3 generations (Nilsson et al., 2008). Granulosa cells isolated from antral follicles of the transgenerational F3 generation vinclozolin lineage ovaries showed epigenetic differences compared to controls. Forty-three genes showed changes in DNA methylation in promoter regions, some of which are known to be correlated with ovarian disease (Nilsson et al., 2012).

Permethrin is an insecticide used to treat both animals and crops (Li et al., 2016). DEET (*N,N*-diethyl-*meta*-toluamide) is the most common active ingredient in insect repellents and is commonly applied topically to the skin (Osimitz and Grothaus, 1995). Following exposure of F0 generation gestating female rats to a mixture of permethrin and DEET, the directly exposed F1 generation females showed a decrease in primordial follicles, indicating a lower follicle pool size. The non-exposed F3 generation rats also experienced a decrease in primordial follicle numbers, and an increase in both small and large cyst frequency as compared to F3 non-exposed vehicle control rats (Nilsson et al., 2012) (see Table 1). In addition, the incidence of F3 generation females with an altered age of puberty was increased (Manikkam et al., 2012b). This demonstrates a transgenerational effect.

Dichlorodiphenyltrichloroethane (DDT) is an environmentally persistent insecticide that was heavily used in the United States until its use was banned 1972. Exposure to DDT may occur when consuming meat, fish, or dairy products (CDC, 2016). Following

Table 1 Toxicants having evidence of transgenerational effects on female reproduction

<i>Environmental toxicant</i>	<i>Transgenerational effect</i>	<i>References</i>
Vinclozolin	Ovarian oocyte decrease, cyst increase, granulosa cell gene expression change. Uterine bleeding	Nilsson et al. (2008, 2012)
Pesticides mix	Ovarian oocyte decrease, cyst increase. Altered pubertal age	Nilsson et al. (2012) and Manikkam et al. (2012b)
DDT	Ovarian cyst increase	Skinner et al. (2013)
Methoxychlor	Ovarian cyst increase	Manikkam et al. (2014)
Plastics mix	Ovarian oocyte decrease, cyst increase. Altered pubertal age	Nilsson et al. (2012) and Manikkam et al. (2012b)
DEHP (mice)	Ovarian oocyte decrease, reduced embryo viability	Pocar et al. (2017)
BPA (mice)	Altered ovarian gene expression	Berger et al. (2016)
Dioxin	Ovarian oocyte decrease, cyst increase. Altered pubertal age (rats). Reduced pregnancy rates, increased pre-term birth, endometriosis (mice)	Nilsson et al. (2012) and Brunner-Tran and Osteen (2011)
Jet fuel	Ovarian oocyte decrease, cyst increase. Altered pubertal age	Nilsson et al. (2012) and Tracey et al. (2013)

the treatment of pregnant F0 generation rats with DDT, the transgenerational F3 generation rats had an increase in incidence of small and large cysts compared to controls (Skinner et al., 2013).

Methoxychlor is an insecticide used on agricultural crops and in animal feed (ATSDR, 2002). In rat studies of F0 generation gestating females exposed to methoxychlor, the resulting F3 generation animals showed a transgenerational increase in polycystic ovary incidence (Manikkam et al., 2014).

Bisphenol-A (BPA), dibutyl phthalate (DBP), and di(2-ethylhexyl)phthalate (DEHP) are components of plastics that are environmental toxicants that humans are exposed to on a regular basis (Lorz et al., 2002). After F0 generation pregnant female rats were exposed to a mixture of BPA, DBP, and DEHP, the F1 generation females were found to have fewer oocytes in their ovaries, and an increase in small and large cysts. In the F3 generation, there was a transgenerational decrease in oocytes, an increase in small and large cysts, and an increased incidence of females with an altered age of puberty (Nilsson et al., 2012; Manikkam et al., 2013). In a mouse study investigating BPA alone, after F0 generation pregnant animals were exposed it was found that the F3 generation had ovaries with altered expression of hormone receptor, steroidogenic, apoptotic, and anti-oxidant genes (Berger et al., 2016). In a mouse study investigating DEHP alone, following exposure of the pregnant F0 generation animals, DEHP was found to cause reduced oocyte number and reduced embryo viability over several generations of female mice (Pocar et al., 2017).

Dioxin is an organic pollutant that is a byproduct of chemical manufacturing processes. It is a reproductive toxicant and can alter hormone release, and cause developmental issues or cancer when direct exposure occurs (WHO, 2010). Following the treatment of F0 generation gestating female rats with dioxin, the F1 generation treated lineage ovaries were found to have a significant decrease in oocyte numbers. The F3 generation animals also experienced a significant transgenerational decrease in oocyte pool size, as well as a significant increase in the incidence of small cysts, and a decrease in the age of puberty (Nilsson et al., 2012). In mice exposure of F0 generation pregnant animals to dioxin resulted in a transgenerational reduction in pregnancy rates seen in the F3 and F4 generations, as well as a transgenerational increase in the incidence of pre-term birth, and increased uterine pathologies resembling endometriosis (Brunner-Tran et al., 2016; Bruner-Tran and Osteen, 2011).

JP-8 is a hydrocarbon mixture used as fuel for jet aircraft. It has been used as a carrier for pesticides and is commonly applied for dust control on gravel roads (Witzmann et al., 2003). After pregnant rats were exposed to jet fuel, the F1 generation directly exposed animals experienced a decrease in oocyte numbers, as well as an increase in small ovarian cysts. The F3 generation showed a transgenerational decrease in oocyte numbers, as well as an increase in the incidence of both small and large cysts, and a decrease in the age of puberty (Nilsson et al., 2012; Tracey et al., 2013).

As can be seen above, epigenetic transgenerational inheritance of female reproductive disease susceptibility can be induced by ancestral exposure to several different environmental toxicants Table 1. The question is raised whether different toxicants promote different epigenetic changes that are passed transgenerationally. A study in rats addressed this question by comparing the DNA methylation patterns in the sperm of the F3 generation descendants of F0 generation gestating females that had been exposed to either vinclozolin, jet fuel hydrocarbons, dioxin, a plastics mixture, or a pesticide mixture (Manikkam et al., 2012a). Interestingly, the sites of changes in DNA methylation, known as differentially methylated regions (DMR), formed a unique pattern with each different ancestral toxicant exposure. No transgenerational DMR was common to all the exposures. This shows that there are molecular epigenetic changes that correlate with inherited transgenerational phenotypes seen with each of these toxicant exposures. This also suggests that DNA methylation patterns could be used as biomarkers to detect ancestral exposure to environmental toxicants. In the future, individuals so tested might then be able to predict whether they have an increased susceptibility to the correlated diseases.

Conclusion

Studies in rodents have shown that environmental toxicants can induce epigenetic changes that can be inherited and lead to an increased incidence of reproductive diseases in females. Care must be taken when interpreting these data since the manifestations of rodent ovarian and reproductive diseases are different from those in humans. However, it is interesting to note that the incidence of human ovarian diseases is now as high as 20% (Sirmans and Pate, 2013), and ancestral exposures to environmental toxicants must be considered as one underlying cause.

Exposure to different environmental factors has the potential to alter the epigenome of an individual, even transgenerationally in subsequent non-exposed generations, which induces changes in reproductive disease frequency. Therefore environmental exposures could contribute to the incidence of reproductive abnormalities in the current human population. Epigenetic profiling of individuals may be able to detect biomarkers of ancestral exposure, and so predict their susceptibility to specific diseases.

Glossary

Body mass index A measurement of body fat adjusted by height and weight.

Endocrine disruptor Chemicals in the environment that modify some aspect of normal hormone function, causing an adverse change in response.

Epidermal growth factor Hormone responsible for cell proliferation, differentiation, and growth.

Estrogen receptor Hormone receptor that can bind endogenous estrogens and estrogen mimicking compounds.

Growth hormone Somatotropin produced by the pituitary gland that stimulates growth, reproduction during early development and maintains tissue during adulthood.

Hepatocyte growth factor Paracrine growth factor found in epithelial, endothelial, mesenchymal, and multiple other tissues that is involved in cell proliferation and motility.

Mammary stem cells Multipotent cells located in the mammary gland, which are capable of self-renewal and differentiation to produce luminal and myoepithelial cell types during different stages of development.

Matrix metalloproteinase Enzymes that degrade the extracellular matrix during growth and regeneration.

Terminal ductal lobular unit Functional unit of the human breast composed of a duct and several clusters of acini that are grouped together in a lobule.

Terminal end bud Highly proliferative structures located at the end of the ducts that promote growth into the mammary fat pad during puberty.

Thelarche The beginning of secondary breast development; often associated with the beginning of puberty in girls.

Vascular endothelial growth factor Signaling protein responsible for stimulating the growth of new lymph and blood vessels.

Introduction

The mammary gland or breast is an exocrine gland that is responsible for producing milk to nourish offspring. This organ is the defining characteristic of mammals and encompasses several species including primates (humans, macaques, gorillas, etc.), ruminants (cattle, deer, goats, etc.), rodents (mice, rats, rabbits, etc.), and many others. Similar to other glandular structures, the mammary gland is susceptible to developing cancer and remains the most commonly diagnosed cancer among females in the United States and many other industrialized countries ([Breastcancer.org, 2017](#); [World Cancer Research Fund International, 2017](#)). Heritable factors contribute to approximately 15% of breast cancer cases, whereas the remaining cases are associated with risk factors that cannot be altered, such as sex, age, race, age at menarche and menopause, and breast density, as well as factors that may be controlled. These can include lifestyle and environmental factors that include, but are not limited to, parity, physical activity, contraceptives use, and chemicals in the environment that are occupational hazards or unintentional exposures ([American Cancer Society, 2017](#); [Rudel et al., 2011](#)).

In addition to breast cancer, early breast development in young girls (aged 6–8 years), prior to other signs of puberty, has become quite common. Over the past five decades, the age of breast bud development has steadily declined in the United States and in several European countries ([Juul et al., 2006](#); [Herman-Giddens et al., 1997](#); [Lindgren, 1996](#)). Differences in age at breast development by race and ethnicity have been noted in the United States, where breast development occurs much earlier in African American females compared to Hispanics, white non-Hispanics, and Asians; however the overall trend remains that precocious puberty is occurring in all races and ethnicities ([Biro et al., 2013](#); [Wu et al., 2002](#)). Body mass index (BMI) plays a role in breast developmental timing, but recent studies that adjusted for BMI and socioeconomic status found that thelarche is significantly earlier in their populations, indicating that there are other factors strongly influencing this developmental endpoint. Therefore, understanding breast development is essential to understanding how nonheritable factors may modify both pubertal breast timing and breast cancer risk.

Life Stages of Normal Mammary Gland Development

Mammary gland morphogenesis is a unique and intricate process that requires extensive crosstalk between multiple endocrine, paracrine, autocrine, and cellular networks during each stage of development regardless of species (Fig. 1). There are however, fundamental intra- and interspecies similarities and differences that exist.

Rodents

During mid-pregnancy in the rodent, rudimentary mammary placodes arise from the ectoderm. Maternal hormones and crosstalk between the fetal mammary epithelium and estrogen receptor (ER)-rich mesenchyme promote the formation of a primary ductal tree that is present before birth (LaMarca and Rosen, 2007; Saji et al., 2000; Feng et al., 2007; Veltmaat et al., 2003). The maternal hormones estrogen and growth hormone are released and enter the placenta where they are introduced into fetal circulation and signal to receptors located on epithelial and/or stromal cells. Binding of estrogen to the ER- α in the fetal mammary stroma induces hepatocyte growth factor (HGF), which is required for epithelial branching (Cunha et al., 1997). As a result, by embryonic day 12 (E12) a bilayered duct forms, comprised of an inner luminal compartment and an outer monolayer of cap cells that eventually develops into the myoepithelial layer (Fig. 2; Silberstein, 2001). By E13–14, male gland development in some mouse strains begins to digress (Richert et al., 2000). In females, the gland progresses into a bulbous structure that continues to elongate until it penetrates the mammary fat pad (~E17). In contrast, the male mouse gland undergoes complete regression caused by testicular development and increased androgen production and release (Richert et al., 2000). Stalk retraction occurs within 2 days of this process due to the epithelium detaching from the epidermis resulting in limited to no epithelium in the male mouse fat pad and no nipple or areola formation. Male rats, on the other hand, possess epithelium in the mammary fat pads, but like mice, have no nipple or areola. In at least one rat strain, development in both sexes was similar at E15.5 and consisted of epithelium concentrically arranged and subjacent to the epidermis (Filgo et al., 2016). Bud growth remained static up to E17.5, but continued to penetrate the fat pad. By E18.5, female rat mammary buds began to invaginate to prepare for nipple development (E19.5). At the same time, male glands continued to progress into the fat pad, but underwent “bud destruction” and invagination to form a nipple did not occur, again due to endocrine cues from the male testes (Filgo et al., 2016). Prior to birth, mammary sprouts from male and female rats and female mice reach a secondary fat pad precursor where it promotes ductal branching and the formation of a rudimentary ductal tree (Filgo et al., 2016). At the time of birth, regardless of strain or sex, the mammary gland consists of rudimentary epithelial stalks and stroma, consisting of fibroblasts, connective tissue, immune cells, and large adipocytes (Richert et al., 2000). Growth remains consistent with other body size increases until puberty.

The prepubertal rodent gland often consists of a single or double layer of epithelium that surrounds a central lumen. With the onset of puberty, exponential gland growth results in ductal elongation and lateral branching. During early puberty, highly proliferative structures known as terminal end buds (TEBs) appear and are prominent until 6–7 weeks of age in rats and mice. The TEBs are teardrop-shaped structures located at the end of the extending ducts of the gland and contain four to six layers of cuboidal epithelial cells, where cap cells are located on the basal surface situated just below the basal lamina (Russo and Russo, 1996). Cap cells are thought to have pluripotent characteristics and will form the luminal and myoepithelial compartments

Fig. 1 The growth and function of the mammary gland is affected by numerous endocrine tissues. The many hormones and growth factors that modify development, and transitions between life stages, are produced by endocrine tissues, as well as within the breast. These numerous hormones are targets for endocrine disruption, by environmental chemicals and pharmaceuticals with off-target effects, and when significantly altered can lead to misdirected growth patterns, breast function, and potentially susceptibility to later life disease. GH, growth hormone; EGF, epidermal growth factor. Modified from Macon and Fenton (2013). *Journal of Mammary Gland Biology and Neoplasia* 18(1), 43–61. <https://doi.org/10.1007/s10911-013-9275-7>.

Fig. 2 Structure of the female mammary gland of the mouse, rat, and human during different life stages. In this comparison of the rodent mammary gland and human breast over the life course, mouse and rat tissues are magnified 1.8 times and human tissue is magnified 2.5 times (rat tissues at 4–6 weeks are less magnified than mouse and human tissues at the same age). Evaluation of similar life stages demonstrates the similarities and differences between the rat and mouse mammary glands and the human breast. In childhood, puberty, and adulthood, the mouse demonstrates a more simple ductal morphology (lacks buds and lobule development) than the rat and human. During adult life, all species demonstrate morphological changes in lobule development characteristics reflective of differences in cycle-dependent ovarian hormone levels (E_2 , estradiol; P_4 , progesterone). This figure does not show the cyclic changes in the human breast. Numerous morphological similarities are evident across species during pregnancy and lactation. Regression of the mammary ducts and lobules to a static state is seen late in life in all species. Male tissues are not shown for rats and humans due to the lack of representative data in the literature. Reproduced from IBCERCC (2013). Inter-agency Breast Cancer and the Environment Research Coordinating Committee. Department of Health and Human Services. Breast Cancer and the Environment: Prioritizing Prevention. Available at: https://www.niehs.nih.gov/about/assets/docs/breast_cancer_and_the_environment_prioritizing_prevention_508.pdf (last accessed May 8, 2017).

(Russo and Russo, 1996). Evidence suggests that TEBs are packed with epithelial cells that undergo apoptosis to create the lumen (Humphreys, 1999). As lumen is being created, ductal elongation also takes place as a result of end bud pressure through the stromal compartment (Williams and Daniel, 1983). As new cells are added to the TEB, the extracellular matrix (ECM) begins to constrict which allows for elongation. Matrix metalloproteinase 14 was particularly integral in this process and was elevated in the cells surrounding the TEBs (Szabova et al., 2005). While collagen has been shown to play an essential role in tubulogenesis, it can also bind to the ECM to help create mammary cell shape. The combination of fibroblast growth factor and ECM remodeling by MMP2 and MMP3 causes TEBs to bifurcate, leading to epithelial branching (Silberstein, 2001; Wiseman et al., 2003). ECM remodeling also promotes angiogenesis and increased vascular endothelial growth factor (VEGF) expression during puberty. Adipocytes express an estrogen response element in their VEGF promoter that encourages communication between endothelial cells, epithelial cells, and adipocytes (Liang et al., 2006). Binding of estrogen to ER α in the epithelium also induces amphiregulin (AREG), a natural ligand for the epidermal growth factor receptor, which induces ductal branching (Wiesen et al., 1999). Lateral duct branching may also be inhibited by stromal TGF- β 1 that in turn inhibits the activity of HGF (Soriano et al., 1998). In male Harlan Sprague-Dawley rats, the mammary gland looks identical to the female gland until puberty. Thereafter it begins to form more lobuloalveolar structures with enlarged vacuoles by PND 46, which are completely mature by PND 70 (Filgo et al., 2016). Once lobuloalveolar structures start to form, longitudinal and lateral growth is inhibited resulting in a stunted phenotype compared to age-matched females.

Similar to puberty, pregnancy is governed by many of the same endocrine and paracrine factors. Although gestation length can vary across different strains and species, mammary gland growth during pregnancy and lactation is similar. Early in pregnancy, secondary and tertiary branching is increased to promote alveolar development (Fig. 2). At the same time the majority of adipose tissue is replaced by epithelium surrounded by capillaries (Richert et al., 2000). During late pregnancy, the alveoli fill an extensive portion of the fat pad. Prolactin and progesterone work in concert in preparation for lactation by promoting differentiation of alveoli, the structures responsible for synthesizing and secreting milk. Pathways downstream of progesterone signaling have implicated receptor activator of NF κ B1 and receptor activator of NF κ B1 ligand (RANKL) in alveologenesis. Mammary involution is the final phase of lactation and occurs when milk-producing epithelial cells undergo apoptosis to return the gland to a simple ductal structure. Involution occurs in two distinct phases. In the first phase, apoptosis is triggered and plasmin helps by disrupting the cell-cell interactions with the ECM. During the second phase, remodeling of the basement membrane, collapse of alveoli, and differentiation of adipocytes occurs (Macias and Hinck, 2012), while plasmin works in concert with MMP3 to disrupt the basal lamina and cause premature involution (Simpson et al., 1994). The gland then returns to a resting phase, similar to that seen in the virgin gland.

Humans

Human breast development begins around the 5th week of gestation, when a two to four cell layer “milk streak” or “mammary band” forms from the thickening of the ectoderm (Dabelow, 1957; Hughes, 1949). Involution of the milk streak is involved in condensing the bud below the ectoderm into the mesenchyme where it will become the nipple primordium. The formation of early epithelial ducts appears shortly after week 12 of gestation (Fig. 2). Ultrastructural assessment of the gland in the second trimester fetus shows two distinct epithelial populations, central and basal cells, which share a similar morphology to the basal cells in the epidermis, where glycogen accumulation is greatest. Unlike the mouse where there is one primary duct that extends from the nipple into 5–10 secondary ducts, the human has many lactiferous ducts that will radially extend to form their own separate ductal system with surrounding stroma, separate from neighboring ducts. Between 18 and 21 weeks of pregnancy, fetal epithelial outgrowths begin in the mesenchyme and quickly undergo formation of lumen that become lined with cuboidal cells. During this time the myoepithelium is fully developed. During the third trimester, secondary epithelial buds undergo canalization and the area surrounding the nipple is reduced forming a “mammary pit” (Osin et al., 1998; Tobon and Salazar, 1974). Within the final weeks of gestation, the vasculature surrounding the adipose tissue is increased. Approximately 15–20 lobules composed of lactiferous ducts that connect to the breast surface appear (Javed and Lteif, 2013). The breast epithelium is functional at birth, when hormones from the mother may cause secretory activity in the newborn, but within the first 2 years following birth the gland will begin to involute due to the removal of maternal hormones, resulting in a small ductal tree that is surrounded by fibroblast-enriched mesenchymal tissue (Anbazhagan et al., 1991). At this point, male and female breast morphology is indistinguishable from one another. Both are composed of a ductal tree that extends onto a small indent that is located on the surface of the skin and where breast development can vary between simple blunt-ended tubular structures or well-defined acinar structures (Howard and Gusterson, 2000).

Between birth and puberty, the mammary gland grows in proportion to the body with little to no differences between males and females. Pubertal development in females usually occurs between 8 and 14 years of age (Marshall and Tanner, 1969), but as mentioned earlier, may occur much earlier. Of the few studies that report cellular development from peri-pubertal cadaver tissues, the breast was described as having small bundles of primary and secondary ducts whose distal ends developed into bulbous structures analogous to the rodent TEBs. New branches arise from the main ducts and lateral buds from these structures eventually evolve into alveolar buds that will form clusters around the duct that forms the lobule type 1. This lobule type 1 structure is termed the terminal ductal lobular unit (TDLU) (Russo et al., 1990). TDLUs are reported in some but not all tissues, which may be accounted for by the specimens stage within pubertal development (Fig. 2; Russo and Russo, 2014). TDLU structures are thought to contain an undifferentiated cell population, similar to the TEBs in rodents.

In the clinic, breast development during this period is scored by Tanner staging. Timing of breast development often varies by ethnicity, growth velocity, and levels of exposure to endogenous and exogenous hormones (Javed and Lteif, 2013). During stage I, there is very little glandular tissue and a slight elevation of the papilla (Javed and Lteif, 2013). By Tanner stage II, breast buds begin to form, nipple elevation occurs, and the diameter surrounding the areola widens and this growth is continued into stage III (Tanner, 1962). Tanner stage II (thelarche) is typically when pediatricians diagnose the beginning of puberty. With age advancement, girls can directly enter stage IV, where the nipple and areola enlarge forming a secondary mound on the breast tissue. In some cases, however, girls can transition from stage III to V without ever going into stage IV. During this final stage the breast reaches its adult size and the areola regresses resulting in a loss of the separation of contours. Adult female breasts are composed of 80% fibrous tissue in the form of intra- and extra-lobular connective tissue, where the fat is pushed to the periphery (Fig. 2).

Once breast development is complete, the TDLUs in humans and minor bud development in rodents are hormonally influenced by the menstrual cycle/estrous cycle (Fig. 2). In the virgin postpubertal gland Lobule 1-type (Lob1-type) TDLUs are the predominant structures and are analogous to the TEBs found in rodents. These structures (in both rodents and humans) are the site at which ductal carcinomas arise. Eventually these structures develop to Lob2, which have more lobules per duct (Russo et al., 2005). Transition from Lob2 to Lob3 structures occurs over years with the development of new alveoli, and if pregnancy is not achieved this may not occur. During puberty, male breast tissue does not undergo any additional development with the exception of 4%–69% of males who may develop transient gynecomastia, or increased proliferation of male breast tissue due to estrogen dominance (Lemaine et al., 2013; Braunstein, 1993). This condition tends to correct itself and is only apparent in ~10% of the pubertal male population by age 17 (Ma and Geffner, 2008). This phenomenon can also occur during neonatal development and late adulthood (due to regression of androgen secretion) but the prevalence is greatest during puberty (Javed and Lteif, 2013; Braunstein, 1993; Nuttall, 1979).

During pregnancy, ducts containing the Lob2 and Lob3 eventually develop secretory acinar cells of Lob4 (Russo and Russo, 2014). Following lactation and weaning, glands regress back to predominantly Lob2 structures, while the glands of nulliparous women contain more Lob1. When menopause occurs, all women regardless of childbearing status typically regress back to Lob1 structures.

Mammary Stem and Progenitor Cells

The emergence of improved technologies and differentiating assays has advanced the field of mammary biology and the ability to isolate and characterize mammary stem cells (MaSC) in mice. The defining characteristics of a stem cell are its ability to self-renew and produce multi-lineage cell types. The stem cell portion of the mammary gland is thought to play an essential role in development, differentiation, maintenance, pregnancy, and even carcinogenesis.

Similarities among the human and rodent mammary structure and mammary stem/progenitor populations have shown that there is great conservation of genes that are responsible for these populations (Lim et al., 2010). Gene signatures from flow cytometry sorted FVB/N mice were identified and compared to the gene signatures from flow sorted human breast cell populations, revealing that once normalization for species was accounted for, the cells for both species colocalized into three distinct types (luminal, stromal, and stem or basal cells) (Lim et al., 2010). When they compared transcriptional activity scores from each mouse subtype gene signature to that of the different human cell subtypes it revealed that genes within each subtype were highly conserved across species. Approximately 1200 signature mouse genes for all cell populations corresponded to their human orthologue, with the MaSC population having the highest number of signature genes and best conservation between species. Of these conserved genes, an array of upregulated genes included transcription factors (i.e., p63, *Egr2*, and *Sox11*), cytokeratins (CK5, 14, and 16), and genes associated with the Wnt/ β -catenin and Notch pathways which have been shown to play a role in stem cell maintenance and differentiation (Asselin-Labat et al., 2006; Roarty and Rosen, 2010; Sun et al., 2010). Luminal progenitor and mature luminal cells were observed to have a lower degree of conservation. Luminal progenitor cells expressed *Kit*, *Elf5*, and *Cxcr4*, a gene involved in metastasis of breast cancer, and more mature luminal cells expressed ER α , PR, and the RANKL; qRT-PCR confirmed these findings (Lim et al., 2010). A more recent study detailed the major pathways involved in MaSC maintenance and demonstrated that the Wnt pathway, which is involved in patterning during development, is required (Badders et al., 2009). Signaling of the Wnt pathway leads to stabilization and accumulation of β -catenin which then translocates into the nucleus binding to LEFT/TFC, and results in transcription of various proliferation genes. MaSC increased 6.4-fold when *Wnt1* was overexpressed using a MMTV promoter (Asselin-Labat et al., 2006). Conversely, decreased Notch signaling in the Cbf-1 knockout mouse and p53 $^{-/-}$ mice have resulted in increased MaSC activity, where activity was defined as the transplant repopulating frequency (Bouras et al., 2008; Cicalese et al., 2009). The Δ N63 isoform of the transcription factor p63, which is associated with p53, can induce Wnt signaling and self-renewal capacity, whereas the Δ T-63 isoform is more involved in luminal commitment and the hedgehog pathway (Badders et al., 2009; Li et al., 2008).

The MaSC and Puberty

Several of the genes and signaling pathways identified during the discovery of MaSC are essential during pubertal mammary gland development, a period of extensive epithelial growth (Tiede and Kang, 2011). In the mouse, TEBs are prevalent during this period and contain highly mitotic cells. Within the cap cells of the TEBs resides a pluripotent stem cell population that is capable of self-

renewal and differentiation. Since these structures are increased during puberty it is also thought that the MaSC and luminal populations are increased and genes involved in these processes are also changed to coordinate with the changes in cellular morphology. Exposure to environmental toxicants may alter the MaSC and luminal epithelial cells. Advances in this research may provide details into the initiation, promotion, and progression of cancer by environmental exposure to endocrine disrupting chemicals during early life stages such as puberty.

The MaSC and Pregnancy

Rodents

Emerging evidence has suggested that another type of MaSC may contribute to the alveolar expansion that occurs during pregnancy. Parity-induced mammary epithelial cells (PI-MEC) are thought to originate from cells that have differentiated during pregnancy. Unlike more committed alveolar cells, this population is thought to either de-differentiate or not undergo apoptosis during involution or remodeling after lactation (Wagner et al., 2002). Pregnant double transgenic mice that expressed *Rosa-lacZ* and X-Gal, which identifies β -galactosidase activity in cells, revealed that immediately following parturition most differentiated alveolar cells expressed *Rosa-lacZ*. During involution cells located in close proximity to TDLUs had the greatest X-gal staining and this was also observed in the developing alveoli of subsequent pregnancies. When stained whole tissue from mice undergoing involution was transplanted into the mammary fat pad of virgin mice, ~40% produced outgrowths that were X-gal positive throughout the entire mammary gland. This group also showed that when the PI-MEC population was sorted by flow cytometry that 98% of were CD24+, and a substantial number of them co-expressed CD49f, both markers seen in pubertal stem cell populations. Notably, these cells were also able to form mammospheres, an epithelial cell derived form of the mammary gland that possess stem cell-like properties, in culture, a phenomenon that has been shown to occur with multipotent human cells (Matulka et al., 2007). In other studies, luciferase expressing MaSCs were transplanted into cleared fat pads of 3-week-old mice, followed by induction of pregnancy, and the authors reported that MaSC populations expanded 200-fold followed by an immediate decrease following parturition. Baseline levels were dependent on whether nursing of pups occurred (Tiede et al., 2009). Progenitor cells have also been shown to increase later in pregnancy and during lactation. At GD 18, luminal mammary populations collected from the dam were further sorted by CD61 expression, a marker that can define less differentiated luminal cells from more differentiated cells. A 15-fold decrease in less differentiated luminal cells was reported, compared to an increase in the number of alveolar luminal differentiated cells (Asselin-Labat et al., 2006).

Humans

MaSC identification in the human has not been obtained in the same fashion as rodents due to the ethical issues that surround collection of cells from human subjects. However, human mammary epithelial cells isolated from mammary tissue from healthy individuals undergoing reduction mammoplasties were successfully found to survive, proliferate, and form spheroids in nonadhesive medium while most of the cells experienced cell death (Dontu et al., 2003). These mammospheres contained 8-fold more bi-lineage progenitor cells than freshly cultured human mammary cells. Successive passages produced colonies that contained all three epithelial cell types. Secondary and later spheroid generations were generated from single cells. Secondary cells were found to express $\alpha 6$ integrin, CD10, CK5 with moderate expression of epithelial specific antigen and CK14. Genotyping and transcription confirmation studies identified genes within the Wnt/Frizzled pathways, CXCR4 and transcription factors that are responsible for cell cycle arrest. Further understanding of the roles that MaSC play in development, function, and susceptibility to cancer in the breast is an urgent research need.

Conclusions

The mammary gland undergoes extensive changes and remodeling over the course of an individual's lifetime, and there are numerous similarities of structures and regulatory cues between rodents and humans. With factors such as increased exposure to environmental chemicals that can mimic endogenous hormones, there has been a significant rise in childhood and adult obesity, altered breast developmental timing during puberty, and breast cancer risk. Scientific efforts should continue to focus on how these factors contribute to these risks to increase public awareness, which in turn may lead to modified lifestyle choices and better nutritional and health resources, especially in the most susceptible populations.

Introduction

The cell biology of the mammary epithelium can be most easily visualized in three groups of structures: (1) the cytoskeleton consisting of actin and microfilaments and their interacting membrane molecules that link the cell to its environment via cell–cell and cell–matrix interactions, (2) the cellular structures within which the enzyme reactions catalyze the synthesis and secretion of milk proteins, and (3) the transporters localized to the basolateral and apical plasma membranes as well as to the membranes of intracellular compartments. Set 1 are the structures that anchor the cell in its environment and lead to the formation of an epithelium, one cell or about 20 μm thick, that firmly separates the interstitial environment, providing both nutrients and hormonal signals, from the extracellular environment. Set 2 are the structures that compartmentalize the enzymes that transform nutrient molecules into milk proteins, sugars, and lipids, setting up elaborate secretion mechanisms. The transporters of Set 3 bring nutrient molecules, ions, and trace elements into the cells, regulate their distribution into cellular compartments, and provide a pathway across the apical membrane into the milk space. For a comprehensive review of the current status of the field and the regulation of the development of these structures see the chapter by Anderson and coworkers in Knobil and Neill's *Physiology of Reproduction* (Anderson et al., 2015).

Fine Structure of the Mammary Epithelial Cell

Fig. 1 shows an electron micrograph of a portion of a mammary epithelial cell from a lactating mouse. Lipid droplets and secretory vesicles containing casein micelles are seen toward the apical portion of the cell while a bevy of compartments including the nucleus, mitochondria, Golgi vesicles, the rough endoplasmic reticulum, and lysosomes that carry out the enzymatic work of the cell are found throughout. A section through a myoepithelial cell is seen embedded at the basal surface; these cells with their long processes surrounding the alveoli are stimulated to contract by oxytocin from the hypothalamus/pituitary bringing about ejection of milk from the lumen and out the nipple. The fine fibrils of the basal lamina can be seen at the exterior surface of the basal membrane of the cell. The myoepithelial cells are within this layer. While not apparent in this picture, this is only part of a single cell in a tightly organized layer of epithelial cells that separate the interstitial space that supplies nutrients from the lumen containing the secreted product, milk.

Fig. 1 Electron micrograph of a lactating mammary epithelial cell. Shown are fat droplets (LD) approaching the apical membrane, secretory vesicles containing casein micelles (arrows), the rough endoplasmic reticulum (RER), golgi vesicles (GOLGI), nucleus (NUC), lysosomes (LYS), and mitochondria (*) within the cell. A myoepithelial cell (Myo) is embedded in the basal side of the cell and a capillary containing a red blood cell (RBC) is snuggled up to the basal lamina separating the interstitial space from the epithelial and myoepithelial compartments. A part of the lumen is shown at the upper pole of the cell and the interstitial space occupies the lower right corner of the image.

Structural Elements of the Alveolar Epithelium

The epithelium of all mucosal surfaces is a highly disciplined structure whose basic form is determined both by an internal cytoskeleton and by interactions with neighboring cells and the extracellular matrix. The mammary epithelium is no exception; the cytoskeleton, which defines the intracellular space, is formed by a network of actin microfilaments mostly lining cell borders (represented in *orange* in Fig. 2) as well as keratin intermediate filaments and microtubules composed of α - and β -tubulin; both are represented by the *green wash* in the interior of the cell. These interacting elements give the cells shape and coherence, providing a framework by which both plasma membrane structures and interior organelles are organized. The cytoskeletal elements interact with a variety of transmembrane molecules that link them to neighboring cells or to the basement membrane (Fig. 2). The classic work of Dorothy Pitelka that defined the electron microscopy of these junctions is still relevant 40 years after its publication in 1977 (Pitelka and Hamamoto, 1977). In all cases the extracellular portion of each transmembrane protein specifically interacts with proteins on an adjacent cell or in the extracellular space. Its intracellular portion interacts with an anchoring protein that mediates its attachment to the cytoskeleton. We will first describe the junctions that mediate cell–cell interactions and then the molecules that anchor the cell to the extracellular matrix.

Cell–Cell Interactions

Tight junctions

The tight junction complex that encircles each epithelial cell at its apical pole (Fig. 2) forms a barrier to the flux of molecules across the paracellular pathway between the luminal and intracellular spaces. This barrier is permeable to ions and even to large molecules such as albumin and immunoglobulins during pregnancy, probably allowing synthesized milk components to return to the interstitial compartment. At secretory activation (sometimes termed lactogenesis II) the decrease in plasma progesterone leads to a change in the configuration of the tight junction proteins so that they form a set of ridge-like structures extending across the cell boundary at the apical ends of the cells. These structures completely prevent passage of any molecules across the paracellular pathway, allowing milk components to accumulate in the lumen. Recent studies indicate that the tetraspanin molecules claudin-3 and claudin-8 are localized to the tight junctions of the lactating mammary epithelium (Baumgartner et al., 2017) interacting with the membrane molecule occludin as well as with zonula occludin proteins like ZO-1 which provide a link to the actin cytoskeleton.

Fig. 2 Cartoon illustrating the cell–cell and cell–matrix interactions of the mammary alveolar cell. The cytoskeleton is composed of actin microfilaments, generally localized to the cell borders (*orange*) and the keratin intermediate filaments and microtubules composed of α - and β -tubulin (both represented as *green*). Cell–cell interacting junctions include the tight junction, the adherens junction, the desmosome, and the gap junctions, all composed of a transmembrane molecule that interacts with a specific submembrane protein, which in turn interacts with the cytoskeleton. Hemidesmosomes mediate interactions between the epithelial cell and the myoepithelial cell as well as between the myoepithelial cell and the basal lamina. Integrins mediate interactions between the epithelial cell and the basal lamina. (See text for additional details.)

Adherens junctions

Cadherin makes up a set of sticky transmembrane fibers that encircle many epithelial cells, providing a strong, calcium dependent linkage across the paracellular pathway that stabilizes the epithelium. Cadherin is bound intracellularly to β -catenin which in turn links cadherin to the actin cytoskeleton. β -Catenin in turn interacts with α -catenin. The linkage between cadherin and catenins regulates a number of signaling pathways including the NF κ B, Wnt, and MAPK pathways thought to give cadherins an important role in the regulation of development.

Desmosomes

Desmosomes are composed of plaques of proteins named desmoglein and desmocollin, members of the cadherin family that interact across the lateral borders between epithelial cells. They are transmembrane proteins whose extracellular domains form calcium dependent adhesions with similar structures on adjacent cells; their intracellular domains interact with desmoplakin, a large dumbbell-shaped protein that also binds keratin, providing a link to the cytoskeleton. Desmosomes form strong cell–cell interactions that contribute to development of the mammary epithelium. They also form connections between the epithelial cells and the basal myoepithelial cells. However, desmosomes linking the epithelial cells are rare in the lactating gland, presumably because they would impair the shape change that must occur in order for the lumen to accommodate the accumulating milk during lactation.

Gap junctions

Direct transfer of molecules up to 1500 Da between cells occurs through gap junctions, channels formed by six connexin molecules that aggregate to form a hemichannel. Alignment of two of these hemichannels between cells allows passage of signaling molecules, ions, vitamins, and other small molecules but not macromolecules. Four types of connexins, Cx26, Cx30, Cx32, and Cx43, are expressed in rodent mammary glands, connexins Cx26 and Cx32 are markedly upregulated in lactation. Cx43 is been shown to be associated with myoepithelial cells. Connexins in the luminal cells of the mammary gland are thought to interact with catenins, giving them a role in the regulation of mammary development.

Cell–Matrix Interactions***Integrin-mediated attachment to the extracellular matrix***

Integrins are transmembrane dimers made up of α and β subunits. The most prevalent integrin in the lactating mammary epithelium is integrin $\alpha 5/\beta 1$. Integrins provide an important mechanism by which the mammary epithelium attaches to the basal lamina, a extracellular matrix layer composed of laminin, collagen IV, nidogens (also known as entactins), the proteoglycan perlecan, fibronectin, and a number of other proteins (Maller et al., 2010). In the mammary gland integrins are thought to bind both to laminin and fibronectin in the basal lamina providing a firm anchor to the extracellular matrix. Intracellularly the integrins bind to an intracellular anchoring protein, most often talin which then interacts with the actin-binding protein vinculin. A kinase, focal adhesion kinase or FAK, is often a part of the complex providing a means by which transcription or cell movement can be regulated through the phosphorylation of signaling molecules such as Src and Rac1 when cell matrix interactions are perturbed.

Other transmembrane mediators

Other membrane molecules through which cells interact with the extracellular matrix are DDR1 (discoidin domain receptor 1), dystroglycan, which binds laminin in the extracellular space and interacts with the Ras signaling pathway intracellularly, and the proteoglycans decorin and syndecans-1 and syndecan-4. Although all have been implicated in mammary development, much less is known about their detailed interactions with both extracellular matrix molecules and intracellular anchoring and signaling proteins.

Cell Biology of Milk Secretion

The four major pathways by which nutrients transported to the lactating mammary cell are turned into components of the mammary secretion are shown in Fig. 3. These pathways are (I) the secretory vesicle pathway, responsible for secreting most milk proteins as well as milk sugars, (II) the lipid secretion pathway responsible for secretion of the milk fat globule (MFG), a specialized structure containing the milk triglyceride, (III) a transcytotic pathway responsible for moving immunoglobulins and other molecules from the interstitial space to the milk lumen, and (IV) a variety of membrane channel and transport proteins responsible for transmembrane movement of nutrients, micronutrients, and the ionic components of milk. During pregnancy the paracellular channel (V) is open allowing molecules of all sizes to move between the interstitial and milk spaces. We will now deal in more detail with each of these pathways.

Pathway I. Secretion of Milk Proteins and Sugars

Pathway I begins in the rough endoplasmic reticulum (Fig. 3, RER) where most milk proteins as well the enzymes responsible for synthesis of lactose and oligosaccharides are created. These molecules are transferred to the Golgi compartment for processing of

Fig. 3 Cartoon illustrating the major intracellular compartments and their role in milk secretion. The major milk secretion pathways are (I) protein and lactose synthesis secretion by Golgi secretory vesicles (SV). (II) Lipid secretion as the milk fat globule (MFG). Cytoplasmic lipid droplets (LD) are seen approaching and fusing with the MFG. (III) Transcytosis, some proteins are endocytosed from the interstitial compartment at the basal surface and transported across the cell to be secreted into the lumen. (IV) Membrane transport. Transporter molecules are located at both basolateral and apical surfaces and on intracellular membranes (see [Table 1](#)). (V) Paracellular pathway, open in pregnancy, closed in lactation. Note that desmosomes mediating epithelial cell interactions are lacking in the lactating mammary cell.

proteins including phosphorylation and attachment of oligosaccharides in many cases. Synthesis of lactose and oligosaccharides also occurs in this compartment. Secretory vesicles containing the milk proteins and sugars bud off the Golgi compartment, traveling to the apical plasma membrane, fusing and releasing their contents into the lumen.

Milk proteins

The major proteins synthesized and secreted by this endogenous pathway are the caseins and the so-called whey proteins, α -lactalbumin, β -lactoglobulin (in ruminants and pigs), whey acidic protein (rodents and pigs) and lactoferrin. Caseins are a class of phosphoproteins that make up 20% (humans) to 80% (cows) of the proteins in milk. The major isoforms of casein are α - and β -caseins, hydrophobic molecules that are highly phosphorylated so that they form distinct electron dense structures called micelles in the presence of ionic calcium. κ -Casein is a more soluble glycoprotein found at the surface of the casein micelle. Casein can be separated from the rest of the milk components by centrifugation, by precipitating at pH 4.6 or by enzymatic cleavage, usually with rennin, precipitating the casein as curds used in cheese making.

α -Lactalbumin (LALBA), with a molecular structure similar to lysozyme, is an important co-factor in lactose synthesis increasing the affinity of the enzyme galactosyltransferase for glucose up to 1000 times. Lactoferrin is an 80 kDa highly cationic iron-binding glycoprotein that is a member of the innate immune system. The protein has anti-microbial properties, both by direct action on bacteria and by depriving bacteria of needed iron. Lactoferrin also induces secretion of interferons with antimicrobial activity.

β -Lactoglobulin is a lipid-binding protein similar to retinoic acid binding protein. It is present in the milk of most mammals but not in rodent or human milk. Although it is known to bind fatty acids, its function in milk is not known.

Many proteins present at lower concentrations in milk are thought to be synthesized via the secretory pathway including lysozyme, bile salt stimulated lipase, amylase, the B-12 binding protein haptocorrin, a folate binding protein and many others. The role of bile salt stimulated lipase in triglyceride digestion in the infant is well known, but the exact role of most of the other minor milk proteins requires additional investigation.

Lactose and oligosaccharide synthesis

Lactose is synthesized from glucose and UDP-galactose. Cytoplasmic glucose is transported into the Golgi by the transporter GLUT-1. Glucose is also converted to UDP-galactose in the cytoplasm by a series of enzymes and then transported into the Golgi by the UDP-galactose transporter. In the Golgi compartment glucose and UDP-galactose are combined by the complex of α -lactalbumin and β 4-galactosyl transferase into the major milk sugar, lactose. Lactose is present at very high concentration in the milk of most species (180–200 mM in human milk) and its osmotic activity draws water into the Golgi.

The oligosaccharides in human milk are present at concentrations from 5 to 10 mg/L, similar to the concentration of human milk protein. The core structure has lactose at the initiating end extended by lactose or acetyl glucosamine units and decorated with fucosyl or sialyl units. These compounds are thought to be of great importance in human infants, regulating the intestinal microbiome and potentially stimulating intestinal development.

Pathway II: Secretion of Milk Lipid and Milk Extracellular Vesicles

The milk fat globule

The MFG is a distinct structure with a large core of triglyceride and a membrane, the milk fat globule membrane, containing a variety of proteins, the most abundant of which are adipophilin (ADPH) also known as perilipin 2, lactadherin, xanthine dehydrogenase, butyrophilin, and, in some species, fatty acid binding protein 3. The fatty acids used to synthesize triglycerides are either transported from the plasma into the alveolar cells by a fatty acid transporter, usually FATP6, or synthesized as medium chain fatty acids in the mammary gland itself. These fatty acids are transferred to the endoplasmic reticulum where they are combined with acetyl CoA and channeled toward esterification with glycerol by the enzymes AGPAT1 and AGPAT6. Small lipid droplets formed between the two leaves of the endoplasmic reticulum acquire a coat of phospholipid that mediates budding into the cytoplasm where they interact with ADPH. These cytoplasmic lipid droplets (CLD) travel toward the apical membrane, fusing into larger CLD as they reach the membrane where they eventually bud into the alveolar lumen ([Masedunskas et al., 2017](#)).

Milk extracellular vesicles

Small extracellular vesicles (EV) ranging in size from 50 to 200 nm in diameter are secreted in large numbers into milk (3×10^{12} particles/mL). They are surrounded by a double layer membrane and contain the traditional EV proteins CD9, CD63, CD81, Hsc70, MHC-class II, MFGE-8, and many others as well as both RNA and microRNA. In bovine milk these RNA's are about 58% non-coding RNA and 13% microRNA. They are thought to interact with intestinal cells and regulate intestinal development and immunity in the infant.

Pathway III. Transepithelial Protein Transport—Immunoglobulins and Other Molecules

Immunoglobulins

Sophisticated mechanisms exist to assure that important immunoglobulins made in the immune cells of the mother are transported to the milk at times and in quantities necessary for protection of the neonate from pathogens to which the mother is exposed. Plasma cells, the immune cells that make immunoglobulins, home from the intestine to the mammary gland during lactation and secrete IgA into the interstitial medium. The IgA binds to the polymeric IgA receptor at the basal surface of the epithelial cell and is then endocytosed via clathrin-coated vesicles, sorted into endosomes and subsequently secreted at the apical membrane bound to a portion of the receptor called secretory component ([Kraehenbuhl and Hunziker, 1998](#)).

Albumin and other plasma-delivered molecules

Many other molecules present in the plasma of lactating animals are transported into milk via transcytosis including albumin in rodents, prolactin, insulin, and drugs and toxins. However, much more work is necessary before the pathways for transcytosis of proteins and other molecules are properly understood.

Pathway IV. Transport of Water, Ions, and Trace Elements Into Milk

Major pathways

The major transporters by which nutrients, ions, and trace elements are moved across the membrane barriers in the lactating mammary epithelium are listed in [Table 1](#). Specific transporters exist for movement of these molecules across the basolateral and apical plasma membranes as well as for transport into various intracellular compartments including the RER, Golgi, and mitochondria.

Water

Water is the most abundant constituent of milk transferred passively across both the basolateral and apical membranes of the lactating mammary cell in response to an osmotic gradient. The water transporters aquaporins 1, 3, and 5 have been identified in the mammary gland and are likely responsible.

Monovalent ions

Sodium, potassium, chloride concentrations in milk are lower than those in the mammary epithelial cell, where sodium and potassium concentrations are thought to be maintained by the Na^+/K^+ -ATPase on the basolateral membrane. An electroneutral $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ transporter may be responsible for the concentration of Cl^- in the mammary cell possibly responsible for the low concentration of milk Cl^- .

Calcium

Calcium is present in milk at concentrations of 10–80 mM mostly bound to casein and citrate. Free calcium ion is present at about 3 mM despite an intracellular free calcium level several orders of magnitude lower ([Cross et al., 2014](#)). Calcium influx across the plasma membrane is mediated by Orai1 channels, so-called store operated channels because they open in response to calcium depletion in the endoplasmic reticulum and Golgi vesicles. Calcium ATPases SERCA2 and SPCA2 transport calcium into the endoplasmic reticulum and Golgi vesicles, respectively, where they interact with calcium binding proteins, particularly

Table 1 Some major transporters in the lactating mammary epithelium

Transported molecule	Major transporter		Location	Major function
	Protein	Gene name		
Glucose	GLUT-1	SLC2A1	Basal membrane, Golgi membrane	Glucose transport across the plasma and Golgi membranes
UDP-galactose	UDP-galactose transporter	SLC35A2	Golgi membrane	UDP-galactose transport into Golgi
Fatty acid	Long chain fatty acid transporter FATP6	SLC27A6	Basal plasma membrane	Long chain fatty acid transport into secretory mammary cells
Neutral amino acids	LAT1	SLC3A2, SLC7A5	Basal plasma membrane	System L neutral amino acid transporter
Neutral amino acids; sodium dependent	SNAT1, SNAT2	SLC38A1, SLC38A2	Basal plasma membrane	System A sodium dependent neutral amino acid transporter
Calcium	Calcium release activated calcium channel protein 1	ORAI1	Basal plasma membrane	Calcium release activated calcium channel; regulated by calcium ATPase SPCA2
Calcium	SERCA2	ATP2A2	Endoplasmic reticulum	Sarco/endoplasmic reticulum Ca ATPase
Calcium	PMCA2	ATP2B2	Apical membrane	Transport of cytosolic calcium into milk
Calcium/magnesium	SPCA2	ATP2C2	Golgi vesicles	Golgi calcium transport; activation of ORAI1
Zinc	ZIP5, ZIP8, ZIP10	SLC39A5, SLC39A8, SLC39A10	Basal membrane	Transport of zinc into the cell
Zinc	ZnT2, ZnT4, ZnT5	SLC30A2, SLC30A4, SLC30A5	Intracellular membranes	Zinc transport into endoplasmic reticulum and Golgi compartments
Zinc	ZIP3	SLC39A3	Apical membrane	Transport of zinc from milk into the cell
Iron	TFR (transferrin receptor)	TFRC	Basolateral membrane	Transports transferrin bound iron from the plasma into endoplasmic vesicles
Iron	DMT1 (also called NRAMP2)	SLC11A2	Apical membrane?	Transport of iron across endosomal membrane and apical membrane
Iron	FPN (ferroportin)	SLC40A1	Plasma membrane	Iron exporter
Copper	CTR1	SLC31A1	Basal membrane	Transport of copper removed from plasma ceruloplasmin into the mammary cell
Water	Aquaporins	AQP1, AQP3, AQP5	Basal and apical membranes and internal membranes	Water equilibration across all membranes of the alveolar cell

casein, and ions such as citrate, bicarbonate, and phosphate. Secretory vesicles transfer this calcium into milk. In addition free calcium is transported from the cytosol into milk via a specific plasma membrane calcium ATPase 2 (PMCA2) expressed in the apical membrane. Magnesium is thought to be transported by many of the mechanisms known to transport calcium, but definitive studies are lacking.

Trace elements

Zinc, iron, and copper are important constituents of milk each of which has its own transport pathways. Two major categories of zinc transporters in the lactating mammary gland ([McCormick et al., 2014](#)) move zinc across membranes: the ZIP transporters move zinc across plasma membranes into the cell and from the cell into the milk and the ZNT2 transporters move zinc into intracellular compartments such as the endoplasmic reticulum. Ferric iron in serum is bound to transferrin which binds to transferrin receptor at the basal surface of the cell and is taken up into endosomes where the low pH leads to iron dissociation. The transferrin receptor recycles to the surface and the iron, reduced to ferrous iron is transported into the cytoplasm by the divalent ion transporter, DMT1. Plasma copper is largely bound to the protein ceruloplasmin, a protein that is synthesized in mammary epithelial cells and is present in milk. Current evidence suggests that interstitial copper ions can be removed from ceruloplasmin with a reductase at which point they become available for transport into the cell by CTR1, the only known membrane transporter for copper. Thus the picture that emerges is that plasma copper is rapidly transferred into the mammary gland by CTR1. Within the gland it must be transferred to the secretory pathway by an unknown mechanism, bound to ceruloplasmin and secreted into milk. However, details of this pathway are lacking.

Manganese, selenium, and cobalt

Manganese levels in human milk are in the ng/mL range but tend to be higher in other animals. Selenium is present at concentrations in the ng/mL range but varies with selenium intake. Cobalt is part of Vitamin B12. However, the mechanisms of transfer from the plasma to the milk are not known.

Pathway V. Paracellular Transport

The tight junctions are open in the gland of the pregnant animal allowing passage of molecules as large as albumin. This pathway is responsible for the high concentrations of such diverse molecules as sodium and albumin in the prepartum mammary secretion as well the transfer of secreted components such as lactose into the plasma, preventing build-up of mammary secretion in the lumen prior to the birth of the offspring.

Overview of the Histology and Anatomy of the Breast

Mammary glands are the defining feature of the class Mammalia. In humans, mammary glands, though present in both females and males, are functional only in the postpartum female. Anatomically, the breasts are round protuberances that contain a parenchyma, namely, the epithelial tree or mammary gland proper, and a stroma, represented by adipose tissue and both loose and dense irregular connective tissue. The glands occupy the subcutaneous layer of the anterior and lateral thoracic wall. Each breast contains 15–20 lobes which in turn consist of many lobules. The gland reaches the exterior through the nipple, a protrusion surrounded by a pigmented areola. The breast parenchyma extends from the level of the second or third rib to the inframammary fold, which is at about the level of the sixth or seventh rib, and from the border of the sternum to the anterior axillary line. The posterior surface of the breast reaches the fasciae of the pectoralis major, serratus anterior, external abdominal oblique, and rectus abdominis muscles (Jesinger, 2014).

The breast ductal system is a branching structure that extends from a lactiferous duct that opens at the nipple and ends distally in structures named the terminal ductal lobular units. Such a ductal system represents a lobe. Rats and mice have a unilobular system. In the rhesus monkey there are three to seven lobes that converge to the nipple. Among women, the number of lobes is variable (Going and Moffat, 2004) and physiologically different within the same breast and overtime (Mills et al., 2016). Ultrasound data suggest the presence of 15–20 ducts converging on the nipple whereas 3D modeling of the nipple from serial sections shows that there is a median of 27 ducts (Going and Moffat, 2004). The number of ducts are greater than the number of openings in the nipple (6–8) suggesting that there could be distinct populations of duct; some produce milk while others derive from skin appendages and do not (Going and Moffat, 2004).

Histologically and functionally, as stated above, the breast is made up of two main tissue types, namely, (1) the parenchyma (epithelium), represented by the epithelial cells, whose function it is to generate milk to nourish the growing newborn, and (2) the stroma which surrounds the glandular epithelium. The epithelium is composed of two layers of cells: a continuous luminal cuboidal cell layer and a basally located discontinuous myoepithelial cell layer. The epithelial duct is in intimate contact with fibrous connective tissue and distant from the adipose tissue (Parmar and Cunha, 2004). The stroma or connective tissue surrounding the epithelium is composed of various cell types (fibroblasts, adipocytes, and immune cells), blood vessels, nerves, and an extracellular fibrous matrix of which the main component is collagen (Howard and Gusterson, 2000; Masso-Welch et al., 2000; Richert et al., 2000). In the mature mammary gland, at the distal end of the ducts, there are lobules composed of sacs or alveoli where milk is produced in response to hormonal cues, these structures are called terminal ductal lobular units and are the sites where breast tumors commonly develop starting as intraductal hyperplasias. These terminal ductal lobular units have been classified as types 1, 2, and 3. Again, ducts and alveolar buds are lined with a bi-layered epithelium composed of luminal epithelial cells and myoepithelial cells residing between the luminal epithelial cells and the basement membrane that separates them from the stroma. Throughout development, reciprocal interactions between the epithelium and the stroma are responsible for the morphogenesis of mammary glands. In the early stages of development the mesenchyme plays an inductive role on the morphogenesis of the epithelium.

Fetal Development

Humans

Fetal breast is particularly vulnerable to carcinogenic insults such as synthetic hormones and endocrine disruptors that cause organizational defects that permanently alter the anatomy and function of the gland (Soto and Sonnenschein, 2010). Most of what is currently known about fetal mammary development in humans resulted from observations of postmortem, difficult-to-obtain specimens. Processes involved in morphogenesis have been mostly inferred from animal studies, mostly carried out in mice. Like in rodents, there is individual variability regarding the timing of developmental events. Breast development is visible by 4 weeks of gestation as paired areas of proliferating epithelial cells in the epidermis of the thoracic region. These areas extend in a line from the axilla to the inguinal region and form two mammary ridges or milk lines. By week 6 of gestation, the mammary ridges have regressed back and only two epithelial masses, the mammary buds, are visible and begin to penetrate into the underlying mesenchyme. The epithelium then becomes surrounded by fibroblast-like cells and collagenous stroma. Until week 9 the placode grows further inward (cone stage) and between weeks 10 and 12, the mammary buds sprout from the placode (budding stage) and become lobular in shape creating an indentation along the epithelial–stromal border. Meanwhile the nipple begins to form in the overlying epidermis and the mesenchyme differentiates into fibroblasts, smooth muscle cells, endothelial cells, and adipocytes. At week 15, the epithelium branches into solid epithelial cords (branching stage) which develop lumen at around week 20. The mammary pit is formed as a depression of the epidermis in the region of the nipple. The ductal epithelium first appears as a bilayer of cuboidal cells. The luminal layer rapidly differentiates into secretory cells and the basal layer into

myoepithelial cells. By 6 months of gestation, a rudimentary ductal system has formed and the ducts are separated by fat islands within a fibrous connective tissue. The secretory epithelium becomes functional near the end of gestation in response to lactogenic hormones (Parmar and Cunha, 2004). The human mammary gland develops similarly in female and male fetuses (Howard and Gusterson, 2000).

Mice

The mouse model has revealed most of what is known about fetal development of the mammary gland. Using tissue recombination techniques, it was observed that the main determinant of morphogenesis is the reciprocal interaction between the mesenchyme and the parenchyma (Howard and Lu, 2014; Sakakura et al., 1976). Mouse fetal mammogenesis starts at about embryonic day 10.5 (E10.5) with the formation of two presumptive milk lines. The mammary placodes become visible between embryonic day (E) 11 and 12 and they then develop into mammary buds by E13, which are elevated knob-like structures. During the next day, they invaginate and thus are no longer observable from the exterior. At this time, several layers of mesenchyme condense surrounding the buds in a concentric fashion and they acquire a "light bulb" shape. In male embryos, testicular development results in testosterone secretion, which acts on the androgen-receptor expressing cells in the mammary mesenchyme. At E13.5 the mesenchyme starts condensing around the bud which then separates from the epidermis hindering further epithelial development (Kratohwil, 1971, 1977). In female mouse embryos, after a 24 h resting phase where practically no cell proliferation is observed, the mammary bud sprouts as it pushes through the mesenchyme penetrating the presumptive fat pad made up of a cluster of preadipocytes. Conversion of preadipocytes to adipocytes starts by E18 attaining a characteristic adipose tissue structure neonatally. At E18, the mammary epithelium consists of a rudimentary ductal tree (Balinsky, 1950; Robinson et al., 1999) (Fig. 1). Apart from the action of testosterone described above, fetal mammary gland development in mice does not require the action of other hormones; null mutation of the estrogen-receptor alpha does not alter fetal development (Dupont et al., 2000). However, fetal mammary morphogenesis can be altered by in utero exposure to hormonally active chemicals such as the xenoestrogen Bisphenol-A (Vandenberg et al., 2007). The fact that fetal DES exposure in rodents and humans leads to increased propensity to breast cancer also indicates that the gland is responsive to these chemicals and that the effects of such exposure could be deleterious (Hoover et al., 2011; Soto and Sonnenschein, 2010). Moreover, nuclear ERs and GPR30 are only expressed in the mesenchyme at this developmental stage, thus reinforcing the idea that the stroma plays a central role on morphogenesis (Wadia et al., 2013). Estrogen receptor alpha appears in the mammary epithelium at the end of the fetal period (E18–19) and is clearly more abundant in the epithelium than in stromal cells after birth and throughout postnatal life (Vandenberg et al., 2007).

Prepubertal and Pubertal Development

Humans

The prepubertal breast consists of a rudimentary tree of simple branched ducts and it grows at the same pace as the general body until the onset of puberty. Breast tissue is similar in prepubertal boys and girls. Pubertal rises in estrogen levels cause breast growth in girls and frequently though transiently in boys (Dimitrakakis and Bondy, 2009). Puberty in girls is marked by initiation of ovulation and establishment of menstrual cycles; also, breasts increase in volume and undergo changes in the stroma and glandular tissues. The stroma increases in the amount of fibrous and adipose tissue which constitutes 80% of the adult nonlactating breast (Parmar and Cunha, 2004). Glandular growth occurs as ducts elongate, branch, and form specialized club-shaped structures at the distal end called terminal end buds (TEB) (Russo and Russo, 2004). New branches will originate from TEBs expanding the epithelial tree and originating small ductules or alveolar buds. Alveolar buds are structures that are morphologically more developed than TEBs yet underdeveloped compared to the acinus, that is, the terminal structure present in the mature nonlactating mammary gland. A cluster of alveolar buds is called a lobule. Lobular formation occurs 1–2 years after the first menstrual cycle and the mammary gland develops gradually throughout adulthood and fully if pregnancy happens. The complexity of the lobules depends on the developmental stage of the breast (Fig. 2). Lobules gradually mature from type 1–2 and 2–3, as they increase in area and number of ductules and decrease in cell number. Once sexual maturity is reached, this initial phase of rapid growth ceases. Epithelial proliferation and morphological changes occur during each menstrual cycle (Söderqvist et al., 1997). Each cycle is regulated by the sequential and combined action of estrogen and progesterone: estrogen peaks at the follicular phase which is followed by a second peak during the luteal phase simultaneously with a peak in progesterone levels (Soules et al., 1989). Breast lobules become more complex and bigger in size during the luteal phase of the cycle. The breast of a nulliparous woman contains predominantly lobules type 1 and occasionally lobules type 2 and rarely type 3 (Russo and Russo, 2004). Lobules in parous women undergo a complete cycle of development to type 4 lobules, the state of maximal development of the adult gland when milk needs to be secreted, namely at the very end of pregnancy and after parturition (Parmar and Cunha, 2004).

Mice

In mice, like in humans, the gland grows isometrically until the onset of puberty. Ovarian activity results in increased prepubertal estradiol serum levels by PND14 (François et al., 2017). Estrogens trigger the peri-pubertal growth of the epithelial ductal tree, which results in the development of terminal end buds, the bulb-shaped invasive structure that guides ductal growth. The main

Fig. 1 Schematic of prenatal development of the mouse mammary gland. (A) The epithelial bud is surrounded by dermal mesenchyme (E12.5). (B) The bud invaginates into the surrounding stroma. The fat pad precursor (FPP) starts to differentiate (E14.5). (C) The epithelial compartment elongates, forming the sprout (E16.5). (D) The fat pad (FP) has now differentiated, a prerequisite for ductal growth and branching. The epithelial compartment has now branched forming solid epithelial cords. Lumen formation starts at this point (E18.5). Reprinted with permission from Soto, A.M., Rubin, B.S., Sonnenschein, C. (2007). *Endocrine disruption and the female*. In Gore, A.C. (eds) *Endocrine-disrupting chemicals. Contemporary endocrinology*. New York, NY: Humana Press.

ductal system is produced by this invasive activity, by TEB bifurcation, and by the elongation of the subtended duct. The TEB is characterized by high levels of proliferation producing the cells needed for ductal elongation, and apoptosis which results in patency of the ducts. Once the TEBs reach the edges of the fat pad they regress (Paine and Lewis, 2017).

The mammary gland undergoes developmental changes during each estrus cycle. Depending on the strain, the ductal system of adult, nonpregnant females will exhibit only ducts, which undergo lateral branching, a process regulated by progesterone (Fig. 3). In some strains, alveolar buds may appear during each cycle. These alveolar structures contain a single layer of epithelial cells; they undergo complete maturation during pregnancy, and thus, become fully developed to sustain milk production (Robinson et al., 1995). Lateral buds may elongate to form branches or cleave to form alveolar buds. As branching morphogenesis occurs, the connective tissue within the extracellular matrix is broken down to allow growth of the epithelial structures (Richert et al., 2000).

The mouse mammary stroma is dissimilar to that of the human breast. In the former, a thin layer of loose connective tissue containing sparse fibroblasts surrounds the ductal tree. This stroma is in turn, surrounded by abundant adipose tissue. In humans, instead, ducts are surrounded by loose connective tissue containing abundant fibroblasts and a distinct fibrous stromal component, which is also surrounded by adipose tissue. In mice, the epithelium is in proximity to the adipose tissue, while in humans it is not. In both species, the extracellular matrix (ECM) is composed of the basement membrane separating the epithelium and stroma, and the interstitial matrix filling the spaces among the stromal cells. The ECM is a functionally important structure that plays an important role in ductal morphogenesis. The ECM is a dynamic structure that undergoes remodeling, a process influenced by enzymes secreted by both the epithelial and stromal cells (Howard and Lu, 2014).

(A) Diagram of a TDLU emerging from the extralobular terminal duct (ETD). (B) Diagram depicting the histology of a normal TDLU in the resting nulliparous state, showing the terminal duct and associated acini. (C) Drawing of terminal branching structures from a 15-year-old human breast. An extralobular duct is shown with rudimentary terminal branching structures. True lobules and acini are not yet present. (D) Drawing of TDLUs from a 22-year-old nulliparous human mammary gland having well developed lobules and acini. (E) Drawing of breast structures of a 30-year-old pregnant woman. Note well developed TDLUs. (F) Drawing of breast tissue of a 55-year-old parous menopausal woman. Ducts are dilated, and the TDLUs are atrophied. (G) Drawing of breast tissue of an 80-year-old woman. Marked atrophy of ducts and TDLUs can be seen. Reprinted with permission from Parmar, H. and Cunha, G. R. (2004). Epithelial-stromal interactions in the mouse and human mammary gland in vivo. *Endocrine-Related Cancer*, 11, 437–458.

Pregnancy

Humans

During pregnancy, the breast undergoes changes from a resting to a functional organ in preparation for feeding the newborn. Although the breast is remodeled in every menstrual cycle, it is pregnancy hormones that trigger remodeling to the extent of a fully mature organ. Circulating levels of lactogenic hormones, estrogen, progesterone, and prolactin as well as the metabolic hormones insulin, growth hormone and glucocorticoids orchestrate ductal branching, alveolar morphogenesis, and secretory differentiation (production of lactose). The levels of prolactin increase during pregnancy and induce secretory differentiation by mid-pregnancy.

Fig. 3 Development of female mouse mammary glands throughout life. (A) E18, (B) PND5, (C) 1 month (pubertal) (arrow depicts terminal end bud), (D) 7 months, showing extensive lateral branching (E) lactating gland, and (F) involuting gland 4 days postweaning. Scale bar in (A and B) 500 μ m, in (C through F) 2 mm. LN denotes lymph node.

(Pang and Hartmann, 2007). Specimens taken during pregnancy and lactation are usually from operations due to a cancer diagnosis during these developmental stages. In general, they show similarities with those observed in rodents; the main difference is heterogeneity. Some parts of the breast are showing clear changes like those described in rodents; other areas seem to be resting (Howard and Gusterson, 2000).

Mice

During the first half of pregnancy, mammary growth occurs through a massive proliferation of the epithelium which manifests as enhanced ductal branching and one of alveolar bud formation. This is due to estrogen and progesterone secreted by the corpus luteum, which during pregnancy is under prolactin stimulation in rodents. In humans, it is HCG that maintains the corpus luteum. The stromal compartment is reduced, although there is an increase of capillaries surrounding the alveoli. The alveolar buds cleave to form alveoli which are organized in lobules that fill the fat pad at the end of pregnancy (lobulo-alveolar phase). Alveoli have a layer of epithelial luminal cells that produce milk components. These luminal cells are surrounded by myoepithelial cells that abut the basement membrane. By day 18 of pregnancy, the alveolar cells are already producing milk proteins and lipids; and at parturition the mammary gland is fully functional (i.e., a lactating mammary gland). Lactogenesis 1 begins during the second half of pregnancy with the progressive expression of various genes involved in the synthesis of milk components. In the mouse, the morphological manifestation of this phase is the appearance of cytoplasmic lipid droplets in the mammary epithelium while in humans it is the appearance of alpha-lactalbumin in serum. This phase is thought to be regulated by progesterone, prolactin and/or plasma lactogen, and growth hormone. During this period, progesterone suppresses milk secretion (Neville et al., 2002).

Lactation

Humans

The signal for the breast to begin secretory activity is the drop in progesterone levels just after the placenta is delivered. The infant is nurtured by colostrum, a high protein concentrate including lactoferrin and IgA that is secreted right after birth; and then by milk which starts to be secreted 30–40 h postpartum. Ejection of milk from the breast results from the contraction of the myoepithelial cells surrounding the alveoli. Mechanical stimulus such as suckling and breast massages can aid milk production and breastfeeding (Hassiotou and Geddes, 2013; Pang and Hartmann, 2007).

Mice

Around parturition, the mouse mammary gland undergoes further changes that lead to the secretion of colostrum first and then milk. This phase is referred to as lactogenesis 2 and is characterized by a further increase in the number of expressed milk protein genes, and the presence of lipid droplets and casein in the alveolar lumen. Colostrum is characterized by the presence of

immunoglobulins. This phase 2 requires high prolactin levels and a drastic lowering of progesterone levels. After the beginning of suckling there is a final expansion of the alveolar compartment and a further increase of milk protein gene expression. Lactation is maintained by suckling, triggering oxytocin secretion which is needed for the contraction of myoepithelial cells, and prolactin secretion, which acts in the luminal epithelial cells to maintain milk production (Neville et al., 2002) (Fig. 3E).

Postlactational Involution

Humans

When milk removal from the breasts slows down or stops (weaning), the glandular tissue gradually involutes. The number of epithelial cells in the alveoli decreases and adipocytes repopulate the stroma. Experiments in mice have shown that macrophages are crucial in extracellular matrix remodeling to return the gland to a resting state similar though not identical to that before pregnancy occurred (O'Brien et al., 2012). Typically, there are more type 2 and 3 lobules than in the nulliparous breast.

Mice

Cessation of suckling triggers mammary gland involution. During the first hours, histology reveals engorgement of the alveoli with milk. After 2 days, the process becomes irreversible with signs of tissue remodeling and of epithelial cell death by apoptosis peaking at day 4 (Fig. 3F). After the first 2 days, stromal cells secrete matrix metalloproteinases that break down extracellular matrix. Macrophages are prominently observed during tissue remodeling. At this point, alveoli start to decrease in number giving way to clusters of disorganized epithelial alveolar cells. Simultaneously, adipocytes re-appear in the stroma. Ducts surrounded by dense stroma are now visible and dense stroma is visible around the ducts. The stroma also increases around the clusters of collapsing alveoli. By day 6 massive cell death has already occurred, but apoptotic bodies are still detected. Concomitantly, a large increase in macrophage numbers is observed, which return to nulliparous levels when regression is completed (O'Brien et al., 2010). By day 21 of involution the remodeled gland appears quite like the gland of nulliparous animals, although with somewhat more differentiated glandular development (Richert et al., 2000).

Age-Related Lobular Involution

Humans

As a woman ages, breast lobules involute and the number and size of acini per lobule in the breast decreases. The intralobular stroma is initially replaced by collagen followed by a gradual replacement of both glandular tissue and collagen by fatty tissue (Hutson et al., 1985). Age-related involution is different from postlactational involution; in the later, mammary tissues regress without loss of glandular tissue. The rate and extent of the process varies among individuals; it is more pronounced when the levels of estrogen and progesterone produced by the ovaries decrease signaling menopause. Partial involution has been detected in women younger than 40 years of age and ongoing in women older than 70. Factors other than age and menopause such as obstetrical history can influence age-related involution (Milanese et al., 2006).

Rodents

Mice and rats do not undergo a process similar to human menopause. Aging of the hypothalamus–pituitary–ovarian axis has been studied in more detail in rats than in mice. Cessation of estrus cyclicity is followed by a chronic anovulatory state. In various rat strains this status is referred to as persistent estrus that is characterized by persistent vaginal cornification. Contrary to menopause in women, rat ovaries of persistent estrous animals contain follicles in various stages of development. The mammary glands of old female nulliparous and multiparous mice at 16–20 months of age show features of early pregnancy, clearly indicating the presence of mammotropic hormones (Raafat et al., 2012; Rubin, 2000).

The Marvels of Milk and Lactation

The Evolution of Lactation, and the Benefits of Milk

Lactation is the core reproductive strategy shared by all mammals, which includes the Monotremata (the egg-laying monotremes, the echidna and the platypus), the Marsupialia (birthing altricial young and no true placenta, such as the opossum, the koala, the wallaby and the kangaroo), and the Eutherian mammals (placental mammals accounting for 95% of all mammals, including humans and domesticated livestock). In turn, the composition of milk is the lifeblood of the neonate, and has been evolutionarily-tailored for its developmental needs and the environment it is raised in. The formidable question over the ages has been “why did lactation evolve as an advantageous reproductive strategy some 300 million years ago?” The answer likely comes from several angles. First, the ability of a mother to produce nutritious milk almost certainly conferred an advantage to terrestrial mammals through their ability to nourish undeveloped infants in drier climates with longer intervals between feedings, all while capitalizing on her nutrient intake and reserves. Milk also likely provided hydration through the parchment-like shell of eggs while providing antimicrobial protection by way of proteins such as lysozyme and lipocalins. The nutritive profile of milk was also surely a major advantage, providing an optimal balance of energy, amino acids, fatty acids and minerals for the growing neonate, while at the same time providing a continuous source of water. The ability to produce milk may have also allowed for shorter generation intervals and delayed tooth eruption, and the faster evolution of successful species (Ofstedal, 2002).

Mammary Gland Anatomy as Relates to Milk Secretion

The functional anatomy of the mammary glands varies considerably. The monotremes have “mammo-pilo-sebaceous patches,” a primitive form of the gland that distributes its milk to the neonate via their associated hairs. In other mammals, the mammary glands have either teats (a single opening, the galactophore) or nipples (served by two or more galactophores). Hence, mice, rats, cows, goats and sheep have teats, whereas pigs, rabbits/elephants and humans have nipples with 2, 8–11, and 10–15 galactophores, respectively (Table 1). Some species such as horses, goats and cows have their glands arranged into a suspended udder. Gland location also differs appreciably across species. Those bearing litters and large numbers of offspring have numerous glands positioned ventrally (i.e., mice and pigs) whereas in species such as humans or elephants the glands are located thoracically. Generally speaking, the glands are arranged symmetrically. The teats/nipples also serve as a critical barrier to pathogens, both physically through the presence of a sphincter surrounding the streak canal, and chemically via their secretion of keratins to form a “keratin plug.”

The Initiation of Milk Synthesis

Fascinatingly, the mammary epithelium transitions from a proliferative state during pregnancy to a state of terminal differentiation for the synthesis and secretion of milk, which is collectively referred to as “lactogenesis.” During lactogenesis I, the epithelium assumes many of the properties needed for milk synthesis—redistribution and enhanced activity of organelles, an assumption of polarity to allow basal-to-apical secretion, and increased enzymatic activity as well as the ability to form colostrum. Lactogenesis II, also referred to as secretory activation, corresponds to the initiation of milk flow around parturition, coincident with the movement of milk fat droplets into the lumen, the synthesis of lactose and the parallel movement of water, and the closure of inter-epithelial tight junctions. Once lactation initiates, the continued copious secretion of milk is referred to as galactopoiesis.

Table 1 Comparative mammary gland structure and milk composition in various species. Data are weight percentage

Species	Water	Fat	Caseins	Whey proteins	Lactose	No. of gland pairs	No. of galactophores per gland	Gland positions
	%	%	%	%	%			
Cow	87	3.7	2.6	0.6	4.6	2	1	Inguinal
Human	87	3.8	0.4	0.6	7.1	1	10–15	Thoracic
Mare	89	1.9	1.3	1.2	6.2	1	2	Inguinal
Pig	81	6.8	2.8	2.0	5.5	6	2	Thoracic/abdominal/inguinal
Mouse	74	13.1	7.0	2.0	3.0	5	1	Thoracic/abdominal/inguinal
Blue whale	46	39.4	7.2	3.7	0.4	1	1	Inguinal

Data are adapted from Akers, R.M. (2002). *Lactation and the mammary gland*. Ames, Iowa: Iowa State Press, and Davies, D.T., Holt, C. and Christie, W.W. (1983). *The composition of milk*. In: Mepham, T. B. (ed.) *Biochemistry of Lactation* No. 1., p. 71–117. Amsterdam, New York: Elsevier Science.

The progression through lactogenesis reflects a complex interplay between the local and endocrine environments. A key requirement for lactogenesis I is a subtending basement membrane to which epithelial cells attach via integrins; this physical environment also facilitates the formation of 3-dimensional, single-layered alveoli. The matrix is also crucial for the response to the key endocrine signals—insulin, prolactin, and glucocorticoid. While these hormones synergize to facilitate synthesis of a range of proteins unique to milk, it is the parallel elevation in circulating progesterone that acts as a “brake”; the timing of the subsequent switch to lactogenesis II upon the removal of this “brake” as the result of a decline in circulating progesterone varies between species, ranging from a few days before parturition (i.e., cows) to a few days after (i.e., humans).

The continued synthesis of milk absolutely requires consistent endocrine stimulation, although requirements vary with species, genetics, and environment. Serum prolactin levels must remain elevated for lactation to continue. Elegant historical studies using endocrine ablation strategies also revealed crucial roles for thyroid hormone, adrenal corticoids, and insulin for the continued synthesis of milk (Tucker, 1974). In addition, supplemental growth hormone increases milk yield and is often administered to dairy cows as recombinant bovine somatotropin.

The various stages of lactogenesis can also be recapitulated *in vitro* and *in vivo*. Mammary epithelial cells in their stromal microenvironment can undergo lactogenesis *in vitro* in the presence of combinations of hormones in “whole organ culture.” Isolated epithelial cells can form hollowed spheroids when exposed to extracellular matrices, then can initiate lactogenesis I after hormonal stimulation. Perhaps the most striking model of lactogenesis is “induced lactation” in nulliparous females (such as sheep or heifers), or in males such as bulls, and can also be realized in humans. In this model, exogenous ovarian steroids can mimic all the mammatogenic and lactogenic changes seen during a normal gestation; with frequent milking, the resulting yields and composition are similar to that from a pregnancy-induced lactation (Smith and Schanbacher, 1973).

Milk and Its Composition

At the broadest level, milk comprises an array of proteins, lipids and carbohydrates that are dissolved or suspended in water. Removing the fat layer rich in triglycerides packaged into milk fat globules leaves “skim” milk that can be further separated into the aqueous “whey” (containing water, lactose, soluble proteins such as α -lactalbumin, β -lactoglobulin, lactoferrin and lysozyme, and ions including potassium, sodium and chloride) and the precipitable “casein” fraction (containing casein molecules in their colloidal, micellar form in association with Ca, Mg, inorganic phosphate and citrate).

While many of these molecules are synthesized *de novo* by the epithelium, others are present in milk due to their active or passive transfer directly from the maternal circulation. One should also not overlook that milk contains various somatic cells including those from the immune system as well as epithelial cells shed from the gland. Milk can also transmit beneficial microbes from the mother (Williams et al., 2017), and can support the intramammary growth of external pathogens, leading to mastitis.

The composition of milk differs significantly across species, ranging from dilute milks with a water content of ~90% (as in dairy animals and humans), through to more viscous milk produced by marine mammals such as whales, seals and dolphins that contains ~50% water (Table 1). Generally speaking, the fat and protein contents of milk are positively correlated across species; conversely, the ratio of fat and lactose in milks is negatively correlated. Thus, more dilute milks typically have a higher lactose content, reflecting the fact that lactose draws water into milk due to its osmotic potential.

Lactose and Water Content

Lactose is a disaccharide produced by the mammary epithelium that not only serves as a nutritious carbohydrate but also as the major osmole in milk. Mammary epithelial cells can produce lactose through their unique synthesis of α -lactalbumin, a modifier that enables galactosyl transferase to facilitate the linkage of glucose and galactose to form lactose. While the lactose content of milk is relatively static throughout lactation, the concentration of lactose (or other oligosaccharides) in milk differs appreciably across species, creating differences in the water content of milk. As an extreme, Cape fur seals have evolved mutations in the α -lactalbumin gene that precludes their ability to synthesize lactose (Sharp et al., 2008).

Milk Fat

The composition of triglyceride in milk depends on several key variables, the first of which is the nature of circulating precursors. Roughly speaking, half of the fat in milk triglyceride is derived from preformed fatty acids taken up from the circulation which contribute to the C₁₆ and longer fatty acid chains. For monogastrics, the circulating fatty acid profile largely reflects that of the diet, thereby increasing the abundance of unsaturated fatty acids found in their milk. By contrast, the majority of circulating fatty acids in ruminants are saturated due to ruminal biohydrogenation, yielding milk fat having a higher content of saturated fatty acids. The remainder of the fatty acids in milk triglyceride are synthesized *de novo* by the mammary epithelial cells. The precursors that are available vary with species. In monogastrics, epithelial cells convert high levels of circulating glucose into a pool of cytoplasmic acetyl CoA ready for conversion to fatty acid chains. By contrast, ruminants have low levels of free circulating glucose, but a readily-available pool of the volatile fatty acid, acetate, which can be directly converted to acetyl CoA. In both cases, the newly-synthesized acetyl CoA is then shunted through the malonyl CoA pathway, which elongates the fatty acid chain by two carbons with every round of the fatty acid synthetase enzyme complex. Lastly, ruminants can also direct rumen-derived

β -hydroxybutyrate into fatty acid synthesis as an alternative four carbon primer. In all cases these newly-synthesized fatty acids are then incorporated into triglyceride via glycerol esterification prior to their secretion via pinocytosis of milk fat globules (Bauman et al., 2006).

Genetics also dictates the composition of milk fat and impacts the mechanisms by which it is secreted. For example, among *Bos taurus* dairy breeds, Holsteins and Jerseys differ considerably in the fat content of their milk (approximately 3.6% and 5%, respectively), while polymorphisms in key milk fat synthesis genes such as DGAT1 also account for variation within a breed (Buitenhuis et al., 2014). Furthermore, goats produce a higher proportion of medium chain fatty acids (C_6 , C_8 , and C_{10}) in their milk fat than do cows; goats also secrete milk fat globules in a true apocrine fashion that captures additional cytoplasmic cellular material, compared to the merocrine secretion of exclusive fat droplets by cows during pinocytosis. Recent evidence also highlights that a key regulator of milk fat droplet secretion is oxytocin-induced contraction of the alveoli (Masedunskas et al., 2017). Milk fat synthesis is also sensitive to specific metabolites, as occurs during “milk fat depression.” In this situation, such as in ruminants fed a diet high in unsaturated fatty acids, elevated levels of rumen-derived conjugated linoleic acid can suppress de novo fatty acid synthesis, lowering the fat content of milk without any appreciable effect on the output of other components (Jenkins and Harvatine, 2014).

Milk Proteins

Milk contains an abundance of proteins that literally come in many shapes and sizes. The caseins are a collection of proteins encoded by different genes arising from a common ancestor that are uniquely synthesized by the mammary epithelium. In bovine milk they account for approximately 80% of all protein while this is closer to 30% for humans. The caseins form the hydrophobic micelles that represent the colloidal fraction of milk; not only are they of high biological value for the infant due to their optimal amino acid profile, but the calcium and phosphate that help form these micelles are equally-important for the growing infant. A number of genetic variants of the different bovine caseins have also been described and are increasingly being harvested as separate forms of cow’s milk with different processability and purported health benefits.

As outlined above, α -lactalbumin is also a key protein found in milk due to the abundance required for lactose synthesis. In some species such as pigs, cows, sheep and goats the whey protein β -lactoglobulin is abundant and can exist as genetic variant A and B forms. Humans on the other hand do not synthesize β -lactoglobulin. Similarly, the whey acidic protein is produced in the milk of species such as mice, rabbits, pigs, and the tammar wallaby, but not in humans or other domestic livestock.

Beyond the caseins and major whey proteins, numerous other proteins are found in milk that differ according to species as well as stage of lactation. The immunoglobulins found in the first milk, or colostrum, serve a critical role for the delivery of immunity to the neonate via passive immunity, and are present at concentrations exceeding those in the maternal circulation. The nature of colostrum also varies as a function of the differential importance of various immunoglobulins (IgA, IgG, and IgM) across species, and depending on the relative contribution of transplacental transfer of immunity from the mother to the fetus. Other proteins such as serum albumin are found in milk as the result of tight junction leakage, and are much more abundant in colostrum, during mastitis, and during involution. Lastly, the mammary epithelium synthesizes a diverse pool of proteins including antimicrobial proteins and growth factors having many, potentially unresolved, functions that might benefit the neonate, or even the gland itself.

Vascular and Lymphatic Support

Sustained lactation requires the delivery of adequate nutrients via the vasculature, which also delivers endocrine signals and removes metabolic byproducts. Blood flow to the lactating glands increases dramatically coincident with increased maternal cardiac output at parturition. With the onset of lactogenesis II the mammary epithelium also increases its ability to extract water, nutrients and oxygen (Linzell, 1974). The importance of the blood supply for milk production is emphasized by the fact that approximately 500 units of blood must flow through the mammary gland to produce 1 unit of milk (Linzell, 1974). A complementary lymphatic vasculature drains the extracellular space surrounding the secretory epithelial cells toward the lymph nodes spaced within and around the mammary glands. While drainage of lymph from the glands is normally pulsatile and unidirectional, the frequency this pulsatility increases significantly during mastitis. These same lymphatics also represent a major route for migration of metastatic cancer cells from a primary mammary tumor to distal lymph nodes and other organs.

Regulation of Milk Synthesis and Secretion

Mammals use a range of strategies to deliver milk to their offspring, largely reflecting adaptation to their environment. For example, pups of mice are permanently attached to the teat and feed approximately every 20 min, while sows feed their piglets every hour. At the other extreme, some seals such as the Hooded seal have an extremely short lactation (4 days) when they do not forage, whereas other seals such as the fur seal can forage offshore for weeks before returning to suckle their pups, without any negative impact on their milk production. Hibernating bear sows can go for months without any intake of water or food while raising their altricial cubs. Dairy animals such as cows and goats are routinely milked twice daily. These are but a few of many different lactation “strategies” that have evolved, or have been selected for—combined, they emphasize that the mammary glands have enormous potential for plasticity, although we understand very little about how far and wide these strategies are used across mammals.

The evacuation of milk at the time of feeding or milking is promoted by the actions of oxytocin (or mesotocin in marsupials) through a neuro-endocrine mechanism. Tactile stimulation of the nipple/teat and their papillary nerves leads to the rapid activation of hypothalamic neurons to release stored oxytocin, a 9-amino acid peptide, from the posterior pituitary. Circulating oxytocin then acts via receptors to stimulate the contraction of basal myoepithelial cells woven around the alveoli, and longitudinally around the ducts. In species such as cows and goats having a gland cistern, the first milk to be harvested is from this region, while the subsequent milk comes from the alveolar tissue and peripheral ducts in response to oxytocin-induced milk letdown. Sensitivity to oxytocin is often countered by factors such as stress, whereas conversely it can also become a conditioned reflex leading to precocious milk letdown in response to various external stimuli such as certain sights or sounds.

The range of different milk removal intervals highlights how the rate of milk accumulation and the local control of milk secretion are regulated within the gland. After milk is evacuated from each alveolus, the reduced intramammary pressure coincides with a maximal rate of milk synthesis and secretion, then, as intraluminal pressure increases over time, the rate of milk synthesis slows. The extended accumulation of milk past a critical time (considered to be approximately 18 h in dairy animals) initiates the disruption of tight junctions between epithelial cells, leading to the appearance of various milk constituents (such as lactose) in the maternal circulation. The factors governing the local regulation of milk synthesis continues to be a topic of interest and may reflect the actions of molecules such as serotonin or dimerized α -lactalbumin, as well as through mechanisms such as physical stretch.

Part of the yield potential of the mammary glands is also likely regulated at the local level. An example is the response to unilateral, frequent milking of a dairy animal's udder when one half is milked on a regular schedule ($2 \times$ /day) while the other half is milked more frequently (i.e., $4 \times$ /day); within both halves the epithelium is assumed to experience the same endocrine environment (Wall and McFadden, 2012). While $4 \times$ milking increases the overall yield as expected, there is also a sustained increase in output, even once it reverts back to $2 \times$ /day. Along similar lines, the mammary epithelium within a gland can be asynchronous, given that different alveoli, as well as lobes, differ in their expression of genes encoding various milk proteins (Molenaar et al., 1992). A gland can also apparently compensate for disrupted function in other glands by producing more milk. Position also influences milk yield; the rear quarters of a cow's udder produces approximately 50% more milk than the fore glands, while the anterior glands in pigs produce more milk than those that are posterior. Several studies suggest there may be left/right asymmetry in milk yield and/or composition, while emerging evidence also suggests that the composition of a mother's milk might reflect the sex of her offspring.

For many of the most widely-studied species, the composition of the major milk components is relatively constant over the course of lactation, excluding the abundance of immunoglobulins in colostrum. However, these profiles often reflect that the female has a relatively static plane of nutrition or environment. On the other hand, certain wild mammals have evolved unique lactation strategies that alter milk composition with lactation stage. Perhaps the most fascinating of these is that used by macropod marsupials such as the tammar wallaby to feed two young at strikingly-different developmental stages by producing milks of different composition and volume—a strategy referred to as “asynchronous concurrent lactation.” Of their four glands, one can produce small volumes of an “early lactation” milk that is high in complex oligosaccharides and low in protein and lipid for nourishment of a continuously-attached altricial young. At the same time, an adjacent gland produces larger volumes of a “late lactation” milk that is high in monosaccharides, fat, and proteins including specific late-lactation proteins (Brennan et al., 2007).

Maternal Adaptation to Lactation

The volume of milk produced by a gland is ultimately a function of the number of epithelial cells in the gland, and the secretory activity per cell. At the same time, the composition of milk and its volume dictates the sum amount of nutrients required from the mother. All of these variables must be addressed to ensure a successful lactation, and are realized through significant changes that occur before, during or after parturition. During lactation, a female markedly increases her dry matter intake and selection of energy-dense foodstuffs, concurrent with changes in her gastrointestinal system including hepatic hypertrophy, lengthening of the intestine, increased uptake of various dietary nutrients, and increased renal retention of water and salts. The liver also simultaneously increases its gluconeogenic potential, particularly in ruminants, to provide the massive amount of glucose required for lactose synthesis. These changes become necessary because the mammary gland becomes a net sink for a range of nutrients with the onset of lactation. At the same time, the female changes her metabolic partitioning of nutrients; whereas adipose tissue was a store for triglyceride during pregnancy, it becomes a net exporter of lipids with the onset of lactation, having less sensitivity to insulin and greater sensitivity to hormone sensitive lipase. Consequently, the liberated glycerol and non-esterified fatty acids become available to the liver for glucose synthesis via gluconeogenesis in support of lactation, and to the mammary epithelium for the synthesis of milk lipids. This striking shift in nutrient partitioning between organs in support of lactation has been termed “homeorrhexis.” Perhaps some of the most striking examples of this concept are in wild animals such as seals and bears that must rely on their accumulated lipid stores to sustain lactation during extended foraging periods or hibernation. Lactating females often then enter a postpartum period of negative energy balance as the nutrient demands to support lactation exceed their ability to consume and extract nutrients from the diet, and to access maternal stores. Thus, it is not surprising that lactating females, particularly high-producing dairy animals, are prone to metabolic diseases such as ketosis and hypercalcemia immediately postpartum. One should also not overlook the ability of lactation to control the other essential maternal function, that is, reproduction. In some species, such as humans, lactation leads to anovulation and its associated contraceptive benefits, while in species such as the tammar wallaby, lactation halts development of a blastocyst leading to its dormancy in a state of diapause (Brennan et al., 2007).

The Lactation Cycle

The course of a lactation in terms of overall yield is typically described by a lactation “curve” describing milk yield over time. For a typical modern dairy cow, lactation length is defined as 305 days—it is important to note that this period reflects dairy management practices designed to have animals concurrently pregnant and re-initiating lactation approximately every year. Longer lactations can be realized if milk harvesting is continued. The lactation curve of a dairy cow typically reflects a “peak” of milk output around 4–6 weeks, then declines thereafter. By contrast, milk yield in species such as pigs and rodents increases over time such that greatest output is realized at weaning after 3 weeks; by contrast, humans, guinea pigs and rabbits have a “peak” of yield about half way through a typical lactation. These changes are presumed to reflect changes in cell activity as well as a balance between any change in cell number due to cell growth and death.

The composition of milk is also not fixed, and can change throughout a lactation. The elevated level of protein in milk post-partum reflects the presence of immunoglobulins in colostrum. Following peak lactation in dairy animals, when lactose concentrations are highest, a declining milk yield is associated with a reduction in lactose output, leading to concomitant increases in the concentrations of fat and protein. By contrast, as indicated earlier, other species such as the tammar wallaby change their composition dramatically to meet the different developmental states of the offspring. Similarly, hibernating species such as bears also change their milk composition appreciably during lactation, moreso as a function of their using maternal nutrient stores.

The Future for Lactation and Its Physiology

For the past 166 million years, mammals have relied on lactation as a cornerstone mechanism for species survival. With continued predictions for a drier and hotter environment as the result of climate change alongside less water availability and restricted range, the very biology of successful lactation could be under threat. We also continue to learn about the benefits of milk for developing neonates, and the importance of breastfeeding. And, aided by selection technologies, the emerging market for tailored milk products from dairy animals stands to expand, which may well benefit enormously from gene-editing approaches. At the same time, the prospect for producing various biologics in transgenic animals continues worldwide, albeit at different rates in different countries. Regardless, one can surely not say that the future for the study of milk and lactation biology is without many questions!

Glossary

Alveologenesis The formation of alveoli, which are hollow cavities in the body. In the lungs, alveoli are small air sacs, while in the mammary gland, alveoli refer to hollow sacks lined with epithelial cells that can differentiate into milk producing units.

Arborization Branching of the mammary ducts within the mammary fat pad.

GHIH Growth hormone inhibiting hormone, also called somatostatin.

Gonadotropic hormones Hormones produced by the gonadotroph cells in the pituitary.

Hypophysectomy Removal of the pituitary.

Invaginate To fold inside upon itself.

Lobuloalveologenesis In the mammary gland, the formation of groups of alveoli into functional units that produce and drain milk into ducts that empty into the nipple.

Morphogenetic Processes that control organ formation and function.

Ovariectomize To surgically remove the ovaries.

Parturition The act of giving birth; childbirth.

STAT5 Signal transducer and activator of transcription 5, a transcription factor.

Introduction

The impact of the pituitary on mammary gland function was first discovered in 1928 by Stricker and Grüter when they injected pituitary extracts into ovariectomized rabbits and found that this induced mammary gland development and milk production (Stricker and Grueter, 1928; Riddle, 1940). This discovery was followed by additional analyses of pituitary extracts on the growth of the mammary gland and stimulation of lactation in the 1930s (Nelson, 1935, 1936; Trott et al., 2008). Soon after, several groups identified the pituitary hormone that controls lactation, which we now know as prolactin (Trott et al., 2008). Further supporting the importance of the pituitary in controlling development of the mammary gland, removal of the pituitary (hypophysectomy) abolished lactation in adult guinea pigs (Nelson, 1935). It is now widely accepted that the structure and function of the mammary gland is exquisitely controlled by neuronal and hormonal signaling generated from the hypothalamic/pituitary (HP) axis. Pituitary hormones that directly regulate mammary gland development, such as prolactin, oxytocin and growth hormone, and others that indirectly impinge upon the gland, are necessary for complete morphogenesis and the production and ejection of milk. Neuronal signals from the hypothalamus control synthesis and secretion of these hormones, which in turn relay various signals to the mammary gland. Specifically, prolactin (PRL), growth hormone (GH), and oxytocin (OXT) directly impact the mammary gland by binding to their cognate receptors in the mammary epithelium or mesenchyme. Other pituitary hormones, such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH) regulate mammary gland function indirectly by promoting the synthesis and secretion of the ovarian hormones, estrogen and progesterone (Table 1).

The basic morphological stages of mammary gland development are consistent across mammals and much of what we know about the molecular mechanisms contributing to hormonal regulation of the gland comes from studying developmental processes in genetically engineered mice (Briskin and O'Malley, 2010). Mammary gland development can be divided into three stages: embryonic, pubertal, and pregnancy/lactation (Fig. 7). While the pubertal and pregnancy/lactation stages of development are highly dependent upon the hormonal milieu and input from the HP axis, embryonic mammary morphogenesis is largely independent of systemic hormonal cues. Rather, early formation and growth of the mammary gland depends on paracrine signaling originating in the mesenchyme surrounding the mammary epithelium.

Mammary morphogenesis initiates with the formation of bilateral ectodermal ridges in the ventral skin to form the milk or mammary lines (Macias and Hinck, 2012). These quickly resolve into the mammary placodes, of which there are five on each side of the mouse, by embryonic day 11.5 (E11.5). The placodes then invaginate to form the mammary buds and subsequently primary ductal mammary sprouts. By E18.5 of the mouse, a rudimentary ductal tree has formed that remains morphogenetically quiescent until the onset of puberty. At this stage and those that follow, mammary gland development becomes dependent on hormones synthesized and secreted by the HP axis and its target organs, in particular, the ovary. Hormone-induced elongation and branching of the ductal tree occurs until it extends to the edges of the mammary fat pad. Pregnancy and lactation are considered to be the final stages of mammary development and differentiation. At the onset of pregnancy, tertiary side branching of the ducts and lobuloalveologenesis begins and extends through parturition at which time milk production commences and lactation can occur. When the pups are weaned and lactation ceases, the mammary epithelium undergoes apoptosis and involutes until the gland returns to a near-virgin state both morphologically and molecularly. Remarkably, this process of epithelial expansion, lactational differentiation, and involution can occur repeatedly without exhaustion of the gland and each of these waves of differentiation and remodeling is controlled, in part, by the hormones synthesized and secreted by the hypothalamic/pituitary axis.

Table 1 Impact of pituitary hormones on mammary morphogenesis and lactation

<i>Hormone</i>	<i>Timing</i>	<i>Direct/Indirect</i>	<i>Source</i>	<i>Function</i>
Adrenocorticotrophic hormone (ACTH)	Adult	Indirect	Anterior pituitary	Lobuloalveologenesis, milk production by modulating adrenal production of glucocorticoids
Estrogens (E)	Juvenile	Direct	Ovary	Ductal elongation
Follicle stimulating hormone (FSH)	Juvenile/adult	Indirect	Anterior pituitary	Ductal elongation and side branching by modulating ovarian production of progestins
Glucocorticoids (GC)	Adult	Direct	Adrenal	Lobuloalveologenesis, milk production, suppression of involution
Growth hormone (GH)	Juvenile	Direct/indirect	Anterior pituitary	Elongation of mammary primary ductal sprout and lactation enhancement through IGF1 regulation
Insulin-like growth factor 1 (IGF1)	Juvenile	Direct/indirect	Liver/mammary stroma	
Luteinizing hormone (LH)	Juvenile/adult	Indirect	Anterior pituitary	Elongation of mammary primary ductal sprout
Progestins (P)	Adult	Direct	Ovary	Ductal elongation and side branching by modulating ovarian production of estrogens
Prolactin (PRL)	Pregnancy/lactation	Direct	Anterior pituitary	Tertiary side branching and lobuloalveologenesis
Oxytocin (OXT)	Lactation	Direct	Posterior pituitary	Lobuloalveologenesis, milk production
				Milk ejection and expanded lobuloalveolar development

Luteinizing Hormone and Follicle-Stimulating Hormone

In most cases, ovarian steroids (estrogens and progestins) are essential for mammary morphogenesis, although dietary exposures to conjugated linoleic acids can substitute for estrogens in rodents and possibly other mammals. The production of ovarian steroids relies on pituitary synthesis and secretion of two gonadotropic hormones, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). When the ovaries of prepubertal animals are removed, the mammary glands fail to develop despite a sharp rise in the levels of LH and FSH. Thus, these pituitary hormones have indirect roles on mammary gland development.

Both LH and FSH are peptide hormones that are synthesized and secreted from gonadotroph cells of the anterior pituitary gland (Fig. 1). LH and FSH production and secretion from these cells depends upon the pulsatile release of a 10 amino acid peptide known as Gonadotropin Releasing Hormone (GnRH) from the hypothalamus that then travels through the portal vasculature to the anterior pituitary. Binding of GnRH to its receptors (GnRHR) on gonadotroph cells induces the expression of the genes encoding LH and FSH as well as secretion of the fully functional hormones. In the ovary, LH and FSH bind to their cognate G-protein coupled receptors, LHR and FSHR, and signal through cAMP (cyclic adenosine monophosphate) to coordinate ovarian follicular growth, ovulation, and estrogen and progesterone production. Estrogens, principally 17 β -estradiol (E2), from the ovary promote continued production of LH in a positive feedback loop until ovulation. After ovulation, progestins (primarily progesterone or P4) and estrogens produced by the ovary now act in a negative feedback loop at the hypothalamus and pituitary to inhibit synthesis and secretion of LH and FSH. In addition to sex steroids, LH and FSH induce the production of activin and inhibin, members of the TGF β superfamily of cytokines that also impact mammary gland development.

In addition to ovariectomy/hormone replacement studies, the specific roles of estrogens and progestins within the mammary gland have also been elucidated through examination of mice lacking the receptors for these hormones. Two classes of estrogen receptors (ER) exist: the G protein-coupled receptor, GPER (also known as GPR30) and the nuclear hormone receptors, ER α and ER β , which are each encoded by separate genes, *ESR1* and *ESR2*, respectively. All three of these receptors are expressed in the mammary epithelium and its surrounding stroma. The mammary glands of *ESR1* null mice fail to develop beyond a rudimentary duct, indicating a requirement for estrogen signaling through ER α for ductal elongation. Indeed, both mammary and stromal ER α are necessary for proper ductal outgrowth as demonstrated through transplantation/tissue recombination studies. In contrast, while ER β and GPER can impact mammary epithelial cell proliferation upon ligand binding in vitro, these receptors are not essential for mammary gland growth or development, in vivo.

Progestins signal through binding to the progesterone receptor (PR), a nuclear hormone receptor. Two isoforms of PR exist, PR α and PR β , but unlike the estrogen receptors, PR α and PR β are products of the same gene (*PGR*). Both isoforms of PR are also expressed in the stromal and epithelial compartments of the mammary gland. Mice lacking PR expression (PRKO) display normal

Fig. 1 Hypothalamic/gonadotropin/ovarian/mammary gland axis. The gonadotropins, LH and FSH, are synthesized and secreted from gonadotrophs of the anterior pituitary gland following stimulation by hypothalamic GnRH. LH and FSH act at the ovary to induce production and release of estrogens (E) and progestins (P). These ovarian hormones then stimulate mammary gland ductal elongation and side branching during puberty.

ductal elongation, but are deficient in tertiary side-branching in adulthood and alveologenesis during pregnancy. When PR null epithelial cells are engrafted into wild type mammary stroma, ductal elongation proceeds normally, but the ducts fail to undergo side branching and alveologenesis. Thus, PR is principally necessary for expansion of differentiated structures of the mammary gland. Genetic disruption of PR in the mammary stroma yields phenotypically normal mammary outgrowth, indicating an intrinsic requirement for PR in the mammary epithelium for arborization of the ductal tree and alveologenesis. Notably, progesterone signaling in the mammary gland also primes the gland for responding to prolactin by increasing the expression of prolactin receptors.

Prolactin

As indicated above, prolactin (PRL) was initially identified as a key pituitary regulator of mammary gland function using injections of pituitary extracts into rabbits and analyzing mammary gland responses. Prolactin is a peptide hormone that is produced and secreted by lactotroph cells in the anterior pituitary gland (Fig. 2). Unlike all other anterior pituitary hormones, prolactin does not require a stimulus from the hypothalamus to be synthesized and secreted. Rather, prolactin is chronically negatively regulated by dopamine that is released from neuroendocrine dopaminergic (NEDA) neurons in the hypothalamus. Lactotroph cells have dopamine receptors on their surface, and following dopamine binding, prolactin secretion is reduced. Dopamine secretion from the hypothalamus varies across the light-dark cycle, resulting in regulation of prolactin secretion by the circadian clock. Prolactin also acts as a negative regulator of its own release through a short feedback loop. As prolactin secretion increases, it binds to receptors on hypothalamic neurons, stimulating dopamine production and secretion. In contrast, loss of PRL signaling in mice leads to hyperproliferation of the pituitary lactotroph cells resulting in prolactinomas. Dopamine, and hence prolactin, can also be regulated by gonadal steroids such as estradiol, progesterone, and testosterone. For estradiol, this involves desensitization of NEDA neurons to prolactin, blocking its negative feedback in the hypothalamus and hence, freeing the pituitary from dopamine suppression and inducing prolactin release.

In pregnancy, serum prolactin levels can follow a bimodal pattern wherein this hormone is elevated during early and late gestation/parturition (rodents) or can progressively increase throughout the pregnancy (primates) (Fig. 3). In early pregnancy, elevated prolactin, in conjunction with progesterone, induces extensive proliferation of the mammary epithelium, ductal side branching,

Fig. 2 Hypothalamic/PRL/mammary gland axis. PRL is synthesized and secreted from lactotroph cells of the anterior pituitary gland in response to elevated estrogens during pregnancy. PRL stimulates lactation and differentiation of mammary epithelial cells and is negatively controlled by dopamine that is released by hypothalamic neurons. PRL also feeds back to suppress its own production by inducing dopamine release.

Fig. 3 Hormonal influence on mammary gland morphology during pregnancy, lactation and involution. Serum hormone levels fluctuate greatly during pregnancy impacting mammary gland development and differentiation. In particular, PRL and OXT hormone levels cycle during lactation to stimulate both milk production and ejection during breastfeeding. At weaning, milk-promoting hormones decline and the mammary gland undergoes involution, morphologically returning to a near-virgin state.

and alveologensis. In contrast, when progesterone levels fall in late pregnancy/parturition, the elevated prolactin causes lobuloalveolar differentiation in preparation for milk production.

There are several mechanisms that ensure elevated prolactin signaling during pregnancy. The number of lactotroph cells in the pituitary increases starting in early pregnancy and this is followed by an increase in prolactin secretion. Prolactin production is also regulated by other hormonal and paracrine factors, such as estradiol, progesterone, glucocorticoids, and insulin. Additionally, human placental lactogen, which is structurally similar to human growth hormone and can bind and activate the prolactin receptor, is present at increasing levels as gestation advances. Through these adaptations, increased prolactin signaling is assured as pregnancy progresses in preparation for lactation. Post-partum, prolactin levels are sustained by signals induced by the suckling infant through the nipple, which continues to suppress the short feedback loop and dopamine secretion by the hypothalamus.

In the mammary gland, prolactin binds to its cognate receptor (PRLR) in the mammary epithelia. The prolactin receptor is a single transmembrane cytokine receptor that is associated with two signaling proteins at its c-terminus [Janus Kinase 2 (JAK2) and Signal Transducer and Activator of Transcription 5 (STAT5)]. Binding of prolactin to PRLR induces phosphorylation of JAK and then STAT5. STAT5 then translocates to the nucleus and induces transcription of target genes involved in promotion of the cell cycle (Cyclin D1) and expression of milk proteins such as β -casein, whey acidic protein (WAP), and β -lactoglobulin. Prolactin deficient female mice (*Prl*^{-/-}) are infertile but develop normally branched mammary glands that can be observed in wild type virgin females, however these glands lack terminal or lateral lobules. Rather than forming lobuloalveoli at the ends of ducts, the ducts terminate as blunt or tapered ends. PRL receptor deficient mice are also infertile and have global reproductive abnormalities, yet their mammary morphogenesis is normal until puberty. At this point, the glands maintain terminal end buds but do not form alveoli. Given the reproductive defects, assessing the impact of prolactin and its receptor required transplantation of PRLR glands into wild-type recipient mouse mammary fat pads. This approach revealed that prolactin signaling is not necessary for pregnancy-associated ductal side branching and alveolar bud formation, but is essential for lobuloalveolar development. Notably, heterozygous PRLR null females are fertile, yet they also display incomplete mammary gland development during pregnancy and fail to nurse their first litter, indicating that a threshold level of prolactin production is essential for these processes to occur. Some *Prlr* heterozygous null mice have restored alveologensis and lactational capacity after subsequent pregnancies, depending on the mouse strain, suggesting that repeated low-level hormonal stimulation can overcome this dosage defect.

Notably, genetic disruption of the *Jak2* gene within the mammary epithelium of mice phenocopies the pregnancy-associated defects in branching morphogenesis and lactation observed in *Prlr* null animals, indicating that it is an essential intermediate of

the prolactin receptor in the mammary epithelium. STAT5 is a downstream effector of JAK2 and genetic activation of STAT5 in the mammary gland induces precocious alveolar development in virgin mice, suggesting that it is also important for regulating gland development. However, loss of both STAT5 isoforms, STAT5a and STAT5b, in the mammary gland only recapitulates some of the defects of *Prlr* loss, indicating that while JAK2 is a primary mediator of prolactin signaling, it functions through STAT5a/b and other, as yet unknown, intermediates.

Growth Hormone

During the time that prolactin was identified as a key pituitary hormone that regulated mammary gland development, growth hormone (GH) was also discovered to have a growth-promoting and lactogenic effect, with GH purified from pituitary extracts inducing lactation. This discovery ultimately led to the broad-scale use of growth hormone to increase milk production in dairy cows. GH is a peptide hormone that is produced and secreted by somatotroph cells in the anterior pituitary gland (Fig. 4). The regulation of growth hormone production by somatotrophs is dependent on the balance of two neuropeptides released by the neurosecretory nuclei of the hypothalamus: growth hormone releasing hormone (GHRH) and growth hormone inhibiting hormone (GHIH, also called somatostatin). GHRH stimulates the G protein-coupled receptor, GHRHR, on somatotrophs. This induces cAMP production that then leads to synthesis and secretion of GH. GH is secreted in a pulsatile pattern in response to multiple stimuli, including ovarian estrogens. The inhibitory protein, somatostatin, is produced by numerous organs in addition to the brain and provides a mechanism for suppressing GH release from the pituitary.

Growth hormone binds to its cognate receptor (GHR) in target tissues to elicit its effects. Like PRLR, GHR is a transmembrane cytokine receptor that also signals through JAK and STAT proteins. The specific functions of GH and GHR on the mammary gland were discovered through the use of genetically modified mice. Both GH and GHR deficient mice are smaller than their wildtype littermates and have a stunted and rudimentary mammary ductal tree, indicating that GH signaling is essential in some way for ductal morphogenesis, although a sparse mammary ductal tree can eventually form in GHR deficient animals. The growth hormone receptor (GHR) is detectable in all postnatal stages of mammary gland development, with higher expression in the stroma than in the epithelial compartment, suggesting that the effects of GH could be directly on the mammary epithelium, or indirectly through the surrounding stromal tissue. To distinguish between these possibilities, GHR null mammary epithelium was transplanted into the mammary fat pads of wild type mice. Such transplants were able to undergo normal mammary morphogenesis with complete arborization of the ductal tree. Hence, GH signaling is not required within the mammary epithelium for ductal outgrowth. Further, these studies suggest that GH signaling may act through the mammary stroma or remotely through another tissue that provides another endocrine hormone that controls the mammary gland.

A key mediator of GH action in many tissues is Insulin-like Growth Factor 1 (IGF1). GH stimulates the release of IGF1 from many tissues, including the liver, to generate systemic IGF1. Locally, GH can also stimulate the production of IGF1 from the

Fig. 4 Hypothalamic/GH/liver/mammary gland axis. GH is synthesized and secreted from the anterior pituitary gland following stimulation by GHRH from the hypothalamus. Circulating GH stimulates synthesis and secretion of IGF1 from the liver, which acts on the mammary gland in conjunction with pubertal estrogens to promote ductal elongation. IGF1 negatively feeds back to the hypothalamus to signal release of GHIH (somatostatin), thus inhibiting GH release.

mammary stroma. GH deficient mice have severely reduced IGF1 levels. In addition, genetic disruption of the *Igf1* gene leads to an identical phenotype in the mammary gland as mice lacking the GHR even though they have normal GH levels. Together, these data suggest that the primary target of GH signaling in the mammary gland is regulation of IGF1 which then controls development of the gland. Whether this impact was conveyed through regulation of IGF1 at the liver or mammary stroma required generation of more sophisticated mouse models that only produced IGF1 from the liver. These mice have completely normal mammary gland development, hence GH action on the mammary gland likely involves stimulation of IGF1 production by the liver that, in turn, systemically stimulates growth of the mammary gland. Notably, IGF1 also negatively feeds back to directly inhibit somatotroph production of GH, as well as stimulates release of somatostatin from the hypothalamus.

Adrenocorticotrophic Hormone

Similar to LH and FSH, adrenocorticotrophic hormone (ACTH) exerts its effects on the mammary gland indirectly, through stimulation of glucocorticoids (GC) generated from the adrenal gland. ACTH was first isolated from pituitary extracts in the early 1930s and shown to stimulate adrenal glucocorticoid production. The impact of the adrenal glands on mammary gland function was discovered when removal of the adrenal glands of lactating mice caused cessation of casein secretion and lactational dysfunction. Continued dissection of the pathway was performed with hormonal deletion and restoration experiments in rabbits and rats. Exogenous ACTH induced lactogenesis in pseudopregnant rabbits and treatment with hydrocortisone induced full mammary differentiation and lactogenesis in adrenalectomized and ovariectomized rats. Thus, a role for ACTH in regulation of mammary epithelial secretion and lactation through modulating glucocorticoids was established.

ACTH is a peptide hormone generated by the cleavage of a large precursor protein, pro-opiomelanocortin (POMC). ACTH is secreted from anterior pituitary corticotrophs upon stimulation by hypothalamic corticotropin-releasing hormone (CRH) (Fig. 5). Circulating ACTH binds to the melanocorticotropin receptor (MCR2), a G protein-coupled receptor in the adrenal cortex, which stimulates a cAMP signaling cascade and production of glucocorticosteroids (glucocorticoids), such as cortisol (corticosterone in mice). Glucocorticoids then signal back to the hypothalamus to reduce CRH and subsequently, ACTH production and secretion in a negative feedback loop.

Glucocorticoids/corticosteroids bind to and activate nuclear hormone receptors (GR) that are expressed in the mammary stroma and epithelium. As with most nuclear hormone receptors, GR acts as a ligand-bound transcription factor, inducing or suppressing gene expression through DNA binding. GR also influences gene expression independently of DNA binding, through

Fig. 5 Hypothalamic/ACTH/adrenal/mammary gland axis. CRH, released from the hypothalamus, promotes synthesis and release of ACTH from corticotrophs of the anterior pituitary gland. ACTH stimulates production of glucocorticoids (GC) from the adrenal cortex, which in conjunction with PRL, promote lactation and differentiation of the mammary epithelium. GC negatively feeds back to the hypothalamus and pituitary to inhibit ACTH expression and release.

protein–protein interactions with factors such as phosphorylated STAT5. Corticosteroid treatment paradigms have shown that these agents inhibit involution of the lactating mammary gland. The impact of GR on mammary gland development has been elucidated using genetically engineered mouse models, yet its specific mechanism is not well defined. Mice lacking GR in all tissues die at birth making them unusable for dissection of GR regulation of post-natal mammary development. Transplantation of GR null mammary epithelial cells into wild-type hosts resulted in impaired ductal development of virgin mice, yet there was no overt impact on mammary epithelial differentiation during pregnancy, lactation, or involution. Using a different mouse model that can only express a mutant form of GR that lacks the ability to bind to DNA, the mice are viable and fertile. Females had a reduction in mammary epithelial cell proliferation, decreased ductal arborization, and a lack of alveolar buds. However, they were fully lactationally competent. Lastly, disruption of the GR gene (*NCR31*) only in the mammary gland during pregnancy leads to decreased lobuloalveologenesis that persists through lactation, yet milk protein production is unaffected and pups can be nursed until weaning. Together, these data indicate that ACTH-stimulated production of glucocorticoids regulates mammary ductal morphogenesis but is dispensable for milk production and lactation.

Glucocorticoids can also synergize with prolactin in mammary epithelial differentiation and milk protein gene expression. Furthermore, prolactin and glucocorticoids have been reported to modulate the levels of one another's receptors, supporting a complex interplay between these two hormones in their actions on the mammary gland.

Oxytocin

Oxytocin (OXT) is a nonapeptide that is essential for milk ejection in response to suckling. OXT was the first peptide hormone to be sequenced in the 1950's by Dr. Du Vigneaud, who was awarded the Nobel Prize for his efforts. OXT is necessary for milk ejection from the lobuloalveolar compartments into the mammary ducts, by inducing contraction of the alveolar myoepithelial cells of the mammary gland. Despite the presence of milk in their mammary glands, OXT-deficient mice fail to nurse their young confirming the necessity of this hormone for milk ejection. OXT is also required for continued proliferation and expansion of lobuloalveoli after birth to accommodate the expanding size of the offspring. Interestingly, while OXT also induces contraction of the uterine wall during childbirth, it is not necessary for parturition.

In contrast to GH, PRL, LH, FSH, and ACTH, which are synthesized and secreted from the anterior pituitary gland, oxytocin is released from the posterior lobe (Fig. 6). Synthesized by the neurosecretory neurons in the hypothalamus, OXT is transported in vesicles down axons to the posterior pituitary gland. Suckling stimulates OXT secretion in a pulsatile manner from the posterior pituitary (Fig. 3). Because mammary tissue responds to oxytocin only at very high concentrations and rapidly becomes desensitized, pulsatile secretion of oxytocin is the most effective for milk release.

OXT exerts its function through binding to the oxytocin receptor (OXTR) in the mammary myoepithelial cells which surround the luminal cells of the ducts and alveoli. The number of OXTR in the mammary myoepithelia increases progressively during pregnancy and remains high during lactation. OXTR deficient dams phenocopy those with loss of the OXT ligand indicating that OXTR is the primary mediator of OXT function. OXTR is a G-protein coupled receptor, which transmits signals across the cell membrane using heterotrimeric G-proteins. OXT binding to the OXTR induces stimulation of phospholipase C and intracellular calcium release, resulting in a contractile force in the myoepithelial cells surrounding the milk-producing luminal cells and causing milk

Fig. 6 Hypothalamic/OXT/mammary gland axis. OXT is synthesized in the hypothalamus and released from the posterior pituitary gland in response to suckling. OXT stimulates mammary gland myoepithelial cell contraction to promote milk ejection.

ejection. In the absence of OXT, milk stasis occurs and involution ensues. Hence, OXT is essential for maintaining lactational competency in addition to milk release.

Overall, there has been no single sensory pathway identified that regulates signals from the mammary gland to the oxytocin neurons. Multiple neurotransmitters have been shown to modulate the milk ejection response, with glutamate and noradrenaline transmitting signals from the hypothalamus, and OXT acting on its own neurons to modulate the response. OXT-producing neurons have excitatory glutamate receptors on their cell surface, and injection of a glutamate receptor antagonist into mice blocks suckling-induced OXT release. Activation of sensory nuclei in the medulla is observed following suckling, and these neurons end in the hypothalamus and can act on OXT neurons. Additionally, an increase in noradrenaline in the hypothalamus is observed in response to a suckling stimulus. Hence, it is likely a complex interplay of numerous neurotransmitters that relays the suckling signal to the hypothalamus and pituitary and ultimately stimulates milk ejection.

Putting It All Together: The Integrated Hormonal Milieu

The majority of mammary gland development occurs postnatally at the onset of puberty and is exquisitely dependent on the hormones produced by the hypothalamus and pituitary (Fig. 7). LH/FSH secretion from gonadotrophs stimulates ovarian estrogen production inducing mammary epithelial cell proliferation and elongation of the ducts through the fat pad. Estrogen levels increase dramatically compared to progesterone, augmenting the expression of PR in the mammary gland in a process called “estrogen priming.” Concomitantly, GH secreted from somatotrophs induces systemic IGF1 levels, which then synergize with estrogens to promote extension of the ductal tree with each estrus wave until the ducts have reached the edges of the fat pad. GH also induces

Fig. 7 The hormonal interplay that controls mammary morphogenesis and lactation from birth to post-lactational involution. The hypothalamus controls the production of a diverse set of pituitary hormones that then directly or indirectly stimulate the development, differentiation, and milk release from the mammary gland. Overall, the formation of a fully functional mammary gland involves the complex integration of inputs from several organs including the hypothalamus, pituitary, ovary, liver, and adrenal glands. Termination of suckling ultimately rewires the hormonal circuitry, leading to involution, a process by which unneeded mammary epithelial cells are pruned from the ductal tree. The cyclic process of alveolar expansion and milk production occurs with each pregnancy, providing a dynamic system to ensure offspring viability.

ER expression resulting in a synergistic impact of estrogens and GH (and, indirectly, IGF1) on ductal development. Tertiary side branching of the ductal tree begins in the adult gland and is dependent on LH/FSH-induced ovarian progesterone synthesis and mammary epithelial PR. During pregnancy, progesterone in concert with glucocorticoids and PRL, prepares the gland for lactation. Together, these three hormones promote extensive tertiary side branching and lobuloalveologenesis leading to complete filling of the mammary fat pad with epithelial cells and initiating milk production. Upon parturition, PRL promotes terminal differentiation of the alveoli into milk producing units. OXT, secreted from the posterior pituitary, then induces the contraction of the alveolar myoepithelial cells, stimulating the ejection of milk into the ducts and through the nipple. Suckling promotes OXT release and OXT then stimulates further proliferation and expansion of lobuloalveoli to accommodate increased milk demand. Upon weaning, the mammary gland involutes and returns to a near-virgin state, resetting the gland for pituitary hormone-induced growth and differentiation with subsequent pregnancies.

It should be noted that none of these pituitary-derived hormones act in isolation to promote mammary development and lactation. Instead, they act in concert, often synergistically, to promote postnatal mammary epithelial cell proliferation and differentiation. This system of positive and negative feedback loops from target organs back to the hypothalamus/pituitary uses a cascade of downstream signaling components to finely tune their relative contribution to the hormonal milieu. This culminates in a fully developed mammary gland at lactation that is dependent on the Hypothalamic/Pituitary/Mammary gland axis (Fig. 7).

Overview and Introduction of Endocrine Regulation of the Mammary Gland in Health and Disease

The mammary gland, or breast in humans and some other mammals, is the gland that mediates lactation, that is production of milk providing nourishment for offspring. Both males and females can have glandular mammary tissue. Growth and development of the mammary gland is regulated endocrinologically. Both sexes can be born with rudimentary mammary tissue. In females glandular tissue begins significant development with puberty in response to the release of steroid hormones estrogen and progesterone. Glandular development in males also is stimulated by exposure to estrogen, either exogenously or due to disease induced hormonal imbalances. During pregnancy main actors estrogen and progesterone work in concert with cytokine-like molecules including prolactin to develop a milk-producing gland. For decades it has been recognized that these hormones do not act in isolation but are influenced by a multiplicity of factors including other hormones such as glucocorticoids and androgens to execute normal mammary gland development and influence development of disease (Topper and Freeman, 1980). Benign and malignant diseases occur in the mammary gland. Both types of conditions can be pathophysiologically influenced by endocrine hormone stimulation. For example, fibrocystic disease of the breast has been linked to imbalanced production of estrogen and progesterone and breast cancer risk is modified by estrogen exposure, for example duration of estrogen exposure or post-menopausal exposure to exogenous estrogen and progesterone replacement therapy. Mammary gland tissue is composed of mammary epithelium, fat and connective collagenous tissue supported by vasculature that delivers nutrients and hormones and lymphoid system that drains extracellular fluids and mediates local immune response.

Steroid Hormones

Steroid hormones with significant activity in mammary gland tissue are grouped into two classes: sex steroids (estrogens, progestogens and androgens) and corticosteroids (glucocorticoids). Estrogens include estrone (E1) produced from ovary and fat tissue, estradiol (E2) primarily produced by ovarian follicles but also breast tissue, fat, liver, adrenal gland, and neural tissues, estriol (E3) produced primarily by the placenta during pregnancy and estetrol (E4) produced only during pregnancy by the liver (Simpson, 2003). Progesterone (P4) is a progestogen produced by the ovary and adrenal glands in the absence of pregnancy and by the corpus luteum and placenta during pregnancy. In males estrogens are produced in fat, testes and neural tissue and progesterone in testes and adrenal glands. Androgens typically act as inhibitors of normal mammary gland development but under some conditions can act as growth stimulants for some types of breast cancers (Hickey et al., 2012). Androgens are produced in the adrenal gland and testes in men and ovaries in women. In both females and males the glucocorticoid cortisol is produced by the adrenal gland. Cortisol (F) has many roles in normal physiology and development, most prominently in non-mammary tissue. In the mammary gland it generally acts as a relative survival factor for mammary epithelial cells.

Estrogens, progesterone, androgens, and glucocorticoids are carried from their non-mammary sites of production to the mammary gland through the vasculature or diffuse locally from sites of production within the gland (Fig. 1). From either production site they freely diffuse across biomembranes (Oren et al., 2004) and when in the cytosol can bind to their corresponding nuclear hormone receptors, primarily estrogen receptor alpha (ESR1) and estrogen receptor beta (ESR2) for estrogens, progesterone receptor (PGR) for progesterone, glucocorticoid receptor (Nuclear Receptor Subfamily 3 Group C Member 1 or NRC31) for cortisol and androgen receptor (AR). ESR1 is generally considered (not considering) as growth promoting for mammary epithelial cells and ESR2 as more growth inhibitory (Renoir, 2012). In classical genomic signaling these ligand/receptor bound complexes are translocated to the nucleus where they can act on genomic DNA, either directly through their cognate DNA response elements or indirectly by binding other transcription factors, to mediate alterations in gene transcription (Bojcsuk et al., 2017). Non-genomic actions of steroid hormones can also occur, which, at times, can work together with classical hormone receptor signaling to mediate hormone action (Levin, 2015). Interactions between different steroid hormone receptors may influence their coordinate action (Sikora, 2016). Classical and non-classical hormone signaling produces both transcriptional and protein-protein interactions that influence cell growth, survival and differentiation.

In the mammary gland estrogen is the steroid hormone with the most positive influence on stimulating ductal growth and progesterone acting with estrogen are a critical steroid hormone combination mediating lobuloalveolar differentiation and lactation. Androgens generally act to suppress mammary epithelial cell growth. All four of the steroid hormones estrogen, progesterone, cortisol, and androgens have been shown to influence breast cancer growth. Approximately 70% of breast cancers express ESR1 some of which co-express PGR. AR and GR are also found expressed in specific breast cancer subsets and can be present in the absence of ESR1 and PGR expression. For ESR1 positive breast cancers therapeutic mainstays are anti-estrogen therapies including selective estrogen modulators (SERMs) that interfere with estrogen receptor action and aromatase inhibitors that interrupt production of estrogens.

Fig. 1 Diagram illustrating four different steroid hormones (estrogens E1, E2, E3, and E4), progesterone, cortisol and testosterone active in mammary gland development, their sites of production, interacting receptors and DNA cognate response elements in mammary epithelial cells in women and men and in women during pregnancy. Interacting receptors: estrogen receptor alpha/beta (ESR1/2) for estrogens, progesterone receptor (PGR) for progesterone, glucocorticoid receptor (Nuclear Receptor Subfamily 3 Group C Member 1 or NRC31) for cortisol and androgen receptor (AR) for testosterone. DNA cognate response elements: ERE, estrogen response element for ESR1/2; PRE, progesterone response element for PGR; GRE, glucocorticoid response element for NRC31; ARE, androgen response element for AR.

Cytokine Hormones

Type I cytokine prolactin (PRL) is the major cytokine mediating normal development and physiology of the mammary gland. It is produced predominantly by the pituitary gland and travels to the mammary gland through the vasculature to act endocrinologically (Hovey et al., 2002). It can also be produced locally by the mammary gland and mammary epithelial cells can demonstrate auto-crine signaling where it is both produced and acts on the same cell as well as paracrine signaling acting on a neighboring cell. Prolactin signals through binding to the prolactin receptor (PRLR) and is most closely linked to lobuloalveolar development and lactation in mammary gland development (Horseman, 1999). Growth hormone (GH1) is a Type I cytokine that binds to the growth hormone receptor (GHR) (Kleinberg et al., 2009). Placental lactogens are Type I cytokines produced by the placenta during pregnancy that share structural homology with PRL and GH and can also influence pregnancy-related mammary development (Forsyth, 1994). Local production of Type II cytokines interleukins (IL) 4 and 13 by mammary epithelial cells can contribute to mammary epithelial luminal cell differentiation after binding to the interleukin 4 receptor (IL4R), a dimer composed of interleukin 13 receptor alpha 1 (IL-13R α 1) and interleukin 4 receptor alpha (IL-4R α) (Khaled et al., 2007). A feature of both Type I and Type II cytokine action in the mammary gland is signaling through the Janus kinase (JAK) and signal transducer and activator of transcription (STAT) signaling pathway to regulate gene transcription through DNA elements referred to as gamma-activated sites (GAS) that recognize and bind STAT proteins (Fig. 2). STAT5 is the major actor in mammary gland development whereas STAT3 plays a more predominant role in involution (Furth et al., 2011). Different types of breast cancer sub-types demonstrate different patterns of STAT protein activation (Furth, 2014). GH/GHR signaling also contributes to mammary gland development through stimulation of insulin growth factor 1 (IGF1) signaling.

Parathyroid Hormone Related Protein

Parathyroid hormone related protein (PTHrP) is produced by many tissues including the mammary gland, acts predominantly locally and plays a role in embryonic mammary gland development (Hiremath and Wysolmerski, 2013). It acts through the G-protein coupled parathyroid hormone receptor 1 (PTHrP1) to specify the mammary mesenchyme.

Fig. 2 Diagram illustrating Type I cytokine hormones prolactin, growth hormone and placental lactogens and Type II cytokine hormones interleukins (IL) 4 and 13 active in mammary gland development, interacting receptors, downstream signaling molecules Janus kinase (JAK), signal transducer and activator of transcription (STAT) insulin growth factor 1 (IGF1), and the STAT DNA response element gamma-activated site (GAS). JAK proteins are intracellular proteins that bind to Type I and II cytokine receptors and mediate recruitment and activation of STAT proteins that subsequently translocate to the nucleus of the cell where they can act as transcription factors through binding to GAS elements as well as other transcriptionally active proteins. Prolactin, growth hormone and placental lactogens act as endocrine hormones secreted by the pituitary or placenta and traveling through the vasculature to reach the mammary gland. Prolactin, IL4, and IL13 can exhibit autocrine and/or paracrine signaling. Interacting receptors: prolactin receptor (PRLR) for prolactin and placental lactogens, growth hormone receptor (GHR) for growth hormone, interleukin 4 receptor (IL4R) for IL4 and IL13. DNA response element for STAT proteins: GAS.

Synergy of Endocrine Hormone Action in Normal Mammary Physiology

Given that the normal mammary gland's primary function is to lactate and produce milk, it is essential to appreciate the endocrinological influences and important processes of the female lifespan that influence mammary gland development and lead to lactation. Over the course of her lifetime, a female will undergo birth, puberty, possible pregnancy and lactation, and menopause, all of which are endocrinologically mediated through different patterns of steroid and cytokine hormone stimulation that synergize with downstream growth factors and receptors, to mediate onset and ending and influence mammary gland development and function (Fig. 3). During the embryonic stage of female life, a rudimentary mammary gland develops from ectoderm and mesoderm germ layers influenced by PTHrP action. Neonatal milk production can occur transiently at birth in both sexes, due to high levels of maternal hormones passing through the placenta to stimulate the neonatal mammary tissue. Mammary gland tissue is then generally quiescent until puberty. Release of gonadotropin releasing hormone (GNRH1) from the hypothalamus triggers the pituitary to secrete gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which then stimulate the ovary to cyclically produce estrogens and progesterone. Their cyclic production acts on mammary ductal tissue to stimulate development of terminal end buds that then travel through the mammary fat pad to lead to the development of a branched ductal tree in the mammary gland by the end of puberty (Paine and Lewis, 2017). Mammary epithelial cells experience cyclic rounds of growth stimulation and regression with each menstrual cycle dictated by waves of higher and lower levels of estrogens and progesterone. During pregnancy, a surge of estrogen and progesterone from the ovaries, corpus luteum and placenta stimulate the anterior pituitary to increase production of prolactin and this coupled with synthesis of placental lactogens from the placenta and local production of IL-4 and IL-13 results in milk production and secretion into the alveolar lumens. Milk becomes available to the offspring upon suckling of the nipple. Nipple sucking stimulates the pituitary gland to release the hormone oxytocin (OXT) stimulating contractile action that moves the milk from the alveolar lumens through the ducts to the nipple for ingestion by the offspring. When the offspring are weaned from the mother and the milk is no longer removed from the gland, involution is triggered. A series of changes in hormonal stimulation including immediate changes in patterns of STAT5/STAT3 activation occur, which is followed

Mammary Gland Growth, Development, and Regression Over the Reproductive Lifespan of Women

Fig. 3 Chart illustrating how changes in secretion levels of three major hormones governing mammary gland development (estrogen (E), progesterone (P) and prolactin (Prl)) are related to different stages of mammary gland development over the reproductive lifespan of a woman. Numbers of plus signs (+) indicate higher and lower secretion levels.

by resolution of hormone levels to cyclical pre-pregnancy patterns (Li et al., 1997). Menopause is reached when the ovarian follicle reserve is exhausted and cyclical production of estrogens and progesterone no longer occurs (Hale et al., 2013) and the mammary epithelium regresses. In humans breast density decreases as the proportion of fatty as compared to collagenous stromal tissue increases. Significantly, risk of breast cancer development actually increases with age, coincident with menopause and loss of cyclic hormonal stimulation.

Endocrinology of Breast Cancer and Breast Disease

For many decades hormones have been recognized as factors modifying breast cancer risk for women (Horn and Vatten, 2017) with longer estrogen exposure over a woman's lifetime increasing risk and early life pregnancy and longer durations of breast feeding associated with reduced risk. Men develop breast cancer at much lower frequency than women (Fentiman, 2016). Activation of the estrogen signaling pathway can promote development of mammary cancer associated with mutation of the *BRCA1*, DNA repair associated (*BRCA1*) gene (Wang and Di, 2014) (Fig. 4). Patterns of hormonal stimulation can influence cytokine secretion and the immune environment of the breast (Need et al., 2014). Deregulation of the normal cross-talk between ligand and receptors expressed in different tissue compartments within the mammary gland and the development of autocrine activation of signaling pathways can increase risk of breast cancer development (Hynes and Watson, 2010). Estrogens can also directly mediate genotoxicity (Cavalieri and Rogan, 2010). Benign breast diseases including cyclic breast pain and appearance of solid and cystic lesions are largely hormonally mediated (Santen and Mansel, 2005). Abnormally elevated prolactin or thyrotropin levels can lead to milk production (galactorrhea) in non-pregnant or menopausal women.

Fig. 4 Table illustrating an example of an interaction between deregulation of a steroid hormone signaling pathway (estrogen) and gene mutation (*BRCA1*, DNA Repair Associated (*BRCA1*)) in increasing risk of breast cancer development. Each of the pathophysiological changes individually increase risk of breast cancer development with the combination posing an even higher risk.

Summary

In summary, the mammary gland is an endocrinological organ that is both the target of exogenous hormonal stimulation and creator of its own endogenous hormonal network. Dominant players include steroid hormones, cytokine Type 1 and 2 hormones and their receptors. Some of the same hormonal networks that regulate normal mammary gland development can function as risk factors for breast cancer development when deregulated. Normal development is mediated by a well-orchestrated organization of hormonal signaling both spatially and temporally. Imbalances in hormonal signaling can increase the risk for benign as well as malignant breast disease.

Glossary

Developmental plasticity The idea that tissue/organismal phenotype is not fixed genetically, but is defined dynamically through the course of development by macro- and micro-environmentally defined epigenetic events that affect the developmental program at molecular and cellular levels.

Developmental program The series of molecular, cellular and related biological processes which, together, define events that determine structure and function of tissues, organs, organ systems and organisms.

Developmental trajectory The organizational path defined by a developmental program.

Lactocrine A mechanism by which bioactive factors are communicated from mother to offspring in colostrum/milk as a specific consequence of nursing.

Lactocrine hypothesis The idea that disruption of lactocrine signaling shortly after birth will alter the program and trajectory of development with short-term organizational effects and long-term consequences for health and well-being.

Phenome The totality of genetic, epigenetic and extragenetic (environmental) factors that, collectively, determine organismal phenotype.

Introduction

Lactocrine is a term coined to describe a mechanism by which milk-borne bioactive factors (MbFs) are communicated from mother to offspring in colostrum (first milk) as a specific consequence of nursing (Bartol et al., 2008). Lactocrine transmission of MbFs is a well-recognized mammalian phenomenon (Bagnell et al., 2017; Bartol et al., 2017). Also well-established is the fact that, beyond genetics, maternal effects on organizational events through the course of gestation affect the trajectory of development and, ultimately, offspring phenotype. Such maternal effects do not end at birth, but continue for a period of time postnatally through signals communicated from mother to offspring via a lactocrine mechanism.

A developmental program is defined by the series of molecular, cellular and related biological processes that, collectively, determine phenotype or organismal structure and function. The nature of these events, which occur in time and space, determine developmental trajectory and connect genotype to phenotype. The totality of genetic, epigenetic and environmental factors that determine organismal phenotype constitute the phenome (Houle et al., 2010; Bush et al., 2016). The lactocrine hypothesis for maternal programming of phenotype posits that lactocrine-mediated signaling is a significant part of the phenomic puzzle and, as such, that disruption of lactocrine support will alter the program and trajectory of postnatal development with short-term organizational effects and long-term phenotypic consequences.

Developmental Plasticity

Phenotype is not fixed genetically, but is defined dynamically through the course of development. Consequently, a single genotype can give rise to more than one phenotype. Thus, phenotype is plastic and developing tissues are said to display developmental plasticity. Inherent in this observation is the long-established idea that disruption of organizational events during “critical moments” of development can have lasting consequences (Stockard, 1921). Such “critical moments” (periods of time during which disruption of the normal path or optimal trajectory of development can affect phenotype) vary for different tissues and organs across species and with respect not only to the timing, but also to the nature, magnitude and duration of disruptive events. Therefore, defined at both genetic and epigenetic levels, a program of development can follow optimal or suboptimal trajectories depending upon the environmental and physiological conditions present during critical organizational periods (Kicheva and Briscoe, 2015).

Many tissues, including those of the female reproductive tract and the central nervous system, remain organizationally plastic for a period of time postnatally and are, therefore, subject to developmental disruption with phenotypic consequences (Hanson and Gluckman, 2014; Ismail et al., 2017; Bartol et al., 2017). Neonatal mammals are subject to effects of the environmental conditions into which they are born, including effects of physiologically significant, organizationally important signals communicated in milk.

Milk-Borne Bioactive Factors (MbFs)

Milk is more than food (Hinde and Milligan, 2011). Beyond nutrients, colostrum contains a complex array of bioactive factors (Table 1). Bioactive molecules identified in colostrum and milk include proteins, growth factors and cytokines, native and latent bioactive peptides, oligosaccharides, fatty acid-derived molecules, steroid hormones, and noncoding microRNAs (miRNAs). Peptides and miRNAs can be packaged selectively in and delivered as elements of exosomes (McGough and Vincent, 2016), found in milk and other body fluids. Additionally, lactocrine transmission of information from mother to offspring may occur via maternal somatic cells delivered in milk. Milk-borne immune cells delivered to nursing infants can cross the neonatal intestinal mucosa, enter the bloodstream and accumulate in somatic tissues. Similarly, the presence of stem cells with multilineage potential in breast milk suggests that lactocrine-mediated microchimerism, involving colonization of neonatal tissues by stem cells of maternal origin, could also affect postnatal development and offspring phenotype (Bartol et al., 2017).

Milk can also serve as a conduit for transmission of bioactive factors of environmental origin to nursing young (Bartol and Bagnell, 2012). Both naturally occurring (e.g., phytochemicals) and manmade (e.g., endocrine-disrupting chemicals) environmental factors can be communicated to neonates in milk. Such substances can be introduced into the maternal system via ingestion,

^aBioactive factors identified in mammalian colostrum and/or mature milk.

^bMilk-borne bioactive factors in a given category have been identified in colostrum/milk from one or more of the species listed.

^cBioactive peptides include those bioactive peptides that are encrypted in larger milk proteins.

^dOther peptides/proteins include, Delta Sleep Inducing Peptide, Erythropoietin, Transferrin, Vitamin B12-Binding Protein, Vitamin D-Binding Protein.

inhalation and/or transdermal transport (LaKind et al., 2004). Thus, lactocrine communication can also provide chemical information to nursing offspring related to the nature of environmental conditions to which the lactating dam is exposed. In turn, macro-environmentally modified lactocrine signals can affect the way in which neonates respond and adapt to extrauterine conditions into which they are born (Bartol and Bagnell, 2012).

The Lactocrine Hypothesis, Colostrum and Lactocrine Programming

The lactocrine hypothesis for maternal programming of postnatal development advanced the idea that imposition of a lactocrine-null or lactocrine deficient state from birth will alter the developmental program and trajectory of somatic development with short-term organizational effects and long-term phenotypic consequences (Bartol et al., 2008, 2017). A lactocrine-null condition is defined by the absence of colostrum consumption. This condition can be imposed purposefully or experimentally, by substitution of a milk replacer for colostrum, or by necessity when conditions of disease or drug addiction make consumption of mother's milk inadvisable clinically. A lactocrine deficient condition is imposed upon nursing offspring when the relative availability, abundance and/or quality of colostrum/milk is suboptimal. This can occur naturally in conditions of mastitis, agalactia and/or competition for teat position in litter-bearing species. A unique secretory product of the mammary gland, colostrum forms during late pregnancy as the mammary gland is prepared for lactation. Because colostrum production is transient, and its composition is optimized to support nutritional, immunological and developmental needs of nursing offspring, colostrum intake is a major determinant of neonatal survival and development (Bartol et al., 2017 and references therein).

Asynchronous concurrent lactation (ACL), characteristic of macropodid marsupials, provides an excellent model system for study of lactocrine effects on patterns of offspring development (Bartol et al., 2017 and references therein). In species that display ACL, two pouch young can nurse from adjacent mammary glands that are secreting milk of different composition. Comparisons of developmental characteristics of pouch young nursed normally, on mammary glands functionally synchronous with their age, or asynchronously, on mammary glands functionally ahead of their age, showed that growth and development were influenced markedly by differences in milk composition. Studies of this kind established that maternally regulated milk composition, rate of milk production, timing of milk consumption, and milk intake can affect developmental trajectory and offspring phenotype.

Effects of nursing from birth and the composition of colostrum or milk on patterns of offspring development are also documented for eutherian mammals (Bartol and Bagnell, 2012; Bartol et al., 2017). Information presented in Table 1 documents the fact that colostrum/milk acts as a conduit for lactocrine transmission of a vast array of signaling molecules. From data generated primarily in rodent models, it is clear that neonatal consumption of colostrum affects differentiation and, ultimately, function of anterior pituitary mammotropes, development of other tissues including liver, kidney, spleen and muscle, and maturation of both the immune system and gastrointestinal tract (Bartol and Bagnell, 2012 and references therein). In nursing mice, the array of chemokines in milk affects patterns of hippocampal cell proliferation in the central nervous system with lasting effects on adult spatial memory. Maternal effects on infant behavioral trajectory mediated by milk-borne glucocorticoids were documented in rhesus macaques. Data for dairy calves suggested a role for MbFs in programming of mammary gland development and function. Collectively, observations indicate that maternal effects on postnatal development at multiple levels include functional contributions from colostrum and milk that must be communicated to offspring via a lactocrine mechanism. Generally, available data indicate that lactocrine signaling can have broad ranging effects on patterns of growth and body composition with lasting implications for health (Bartol and Bagnell, 2012). Data for the pig (*Sus scrofa domestica*) provide the most complete picture of lactocrine programming effects, as reflected by studies of the developing female reproductive tract.

Lactocrine Effects on Female Reproductive Tract (FRT) Development

The mammalian uterine wall is incompletely organized at birth (postnatal day = PND 0) (Cooke et al., 2013). In species including the mouse, rat, sheep, and pig, uterine growth and morphogenesis of the uterine wall, including the uterine mucosal lining or endometrium, proceed normally for a period of time neonatally after bilateral ovariectomy at birth. Continued development of the uterine wall after ovariectomy at birth, including differentiation and proliferation of uterine glands, indicates that extraovarian factors support uterine development in the early neonatal period. Data for the pig indicate that one source of such extraovarian support comes from colostrum via a lactocrine mechanism (Bartol et al., 2013, 2017).

In the pig, endometrial glands are absent or rudimentary at birth. Nascent endometrial glandular epithelium (GE) differentiates from luminal epithelium (LE) and begins to proliferate and penetrate uterine stroma (ST) between birth and PND 3. Differentiation of GE from LE and histogenesis of the uterine wall during this period are marked by spatially unique endometrial expression of a number of gene products, including estrogen receptors (ESR1). This period coincides with an optimal window for lactocrine transmission of colostral MbFs to offspring. Protein and other components of colostrum are present at highest concentrations, and are delivered steadily on day 1 of lactation. Gut closure in the pig, the point after which macromolecular components of colostrum may no longer simply diffuse across intestinal epithelium, occurs within approximately 48 h of birth. These relationships are reviewed in detail elsewhere (Bartol et al., 1993, 2013, 2017; Cooke et al., 2013).

Lactocrine signaling from birth affects the porcine uterine developmental program rapidly (Bagnell et al., 2017; Bartol et al., 2017). A single feeding of colostrum at birth is sufficient to support normal levels of uterine and cervical cell proliferation at

12 h postnatal, suggesting that lactocrine effects on FRT development are initiated at first ingestion of colostrum. When colostrum consumption was delayed by milk replacer feeding for 0.5 h from birth, or limited to 12 h from birth, developmental markers including uterine matrix metalloproteinase-9 (MMP9) and tissue inhibitor of metalloproteinase-1, as well as cervical MMP9 expression levels on PND 2 were similar to those observed for nursed gilts that consumed colostrum continuously for 48 h from birth. Since nursing for as little as 1 h from birth is sufficient to establish passive immunity in newborn piglets, observations indicate that lactocrine signals supportive of FRT development are likely to be communicated within 12 h of birth.

Imposition of the lactocrine-null state for 2 days from birth, by feeding milk replacer in lieu of colostrum, affected the neonatal porcine uterine transcriptome profoundly between birth and PND 2 (Bartol et al., 2017). Global RNA sequencing (RNAseq) revealed over 3000 differentially expressed genes associated with uterine development between birth and PND 2 in nursed gilts, whereas over 4500 differentially expressed genes were associated with this period in gilts fed milk replacer from birth. Comparison of uterine gene expression on PND 2 between nursed and replacer-fed gilts revealed over 800 differentially expressed, lactocrine-sensitive genes. Evaluation of small noncoding microRNA (miRNA) expression also revealed unique age and lactocrine effects on uterine miRNA expression between birth and PND 2 in nursed as compared to replacer-fed gilts (George et al., 2017). Integration of uterine RNAseq and small RNAseq data, followed by informatic analyses, predicted lactocrine-sensitive biological processes associated with uterine development during this period to include: cell–cell signaling; cell, tissue and organ development; tissue morphology; and reproductive system development and function.

Beyond effects on the neonatal uterine transcriptome identified in lactocrine-null gilts on PND 2, imposition of the lactocrine-null state for 2 days from birth also altered porcine uterine developmental trajectory as evaluated on PND 14. Compared to nursed controls, endometrial thickness, uterine gland penetration depth, GE and stromal cell proliferation, and ESR1 expression by nascent GE were reduced on PND 14 in lactocrine-null gilts. Thus, experimental disruption of lactocrine support from birth by milk replacer feeding is antiuterotrophic in the porcine neonate.

Consistent with these observations, natural disruption of lactocrine input in nursing piglets, resulting in a lactocrine deficient state, also affects uterine development negatively. Evaluation of uterine wall development on PND 14 in nursed gilts determined to be lactocrine deficient as reflected by low serum immunoglobulin immunocrit (iCrit) on PND 0 (Bartol et al., 2017), revealed effects similar to those observed in lactocrine-null gilts at the same point. Again, endometrial development was generally more advanced on PND 14 in high (optimal colostrum consumption) as compared to low (minimal colostrum consumption) iCrit gilts, indicating an antiuterotrophic effect of lactocrine deficiency from birth.

Long-Term Consequences of Lactocrine Deficiency

The lactocrine hypothesis predicts that disruption of lactocrine signaling will affect the developmental trajectory of lactocrine-sensitive tissues with lasting consequences. This hypothesis was tested retrospectively for the uterus in a study designed to define the relationship between PND 0 iCrit, indicative of the amount of colostrum acquired by piglets on the day of birth, and their fecundity as adults (Bartol et al., 2013). Initial data included observations for 381 gilts for which PND 0 iCrit values were obtained, and live litter sizes were recorded for the same animals as adults. As predicted, low serum iCrit on PND 0, reflecting minimal colostrum consumption (lactocrine deficiency), was associated with reduced lifetime fecundity through four parities (Bartol et al., 2013). This observation was confirmed and extended in a complementary study of the same design involving 799 females (Bartol et al., 2017 and references therein). Results showed that lactocrine deficiency from birth was associated with reduced average preweaning growth rate during lactation, increased age at puberty, and reduced live litter size. The difference in live litter size for adult females that had low as compared to high PND 0 iCrit values was approximately 1.4 piglets per litter, with no effect of parity. These data were interpreted to indicate permanent impairment of reproductive performance in neonatally lactocrine-deficient female pigs (Bartol et al., 2017).

Major reproductive losses in the pig are associated with early embryonic mortality attributable, in part, to endometrial dysfunction during the peri-attachment period of early pregnancy (Bazer et al., 2011). Such losses during early pregnancy could account for differences in live litter size at the end of gestation. To test the hypothesis that permanent impairment of reproductive performance in neonatally lactocrine-deficient adult female pigs is associated with endometrial functionality, uterine tissues were obtained from adult, neonatally low (lactocrine deficient) and high (control) iCrit gilts on pregnancy day (PxD) 13. Effects of lactocrine deficiency at birth on adult, peri-attachment stage endometrial gene expression were determined by RNAseq analysis. Preliminary results indicate hundreds of differential endometrial gene expression events in adults on PxD 13 associated with lactocrine deficiency from birth. Overall, observations for the pig can be interpreted to indicate that disruption of lactocrine signaling for a relatively short period of time from birth: (1) alters the neonatal uterine developmental program with lasting consequences, as reflected by altered endometrial responses to conceptus signals during early pregnancy; (2) reduces uterine capacity for conceptus support; and (3) reduces fecundity, reflected by smaller litters in neonatally lactocrine deficient adults. Collectively, observations support the lactocrine hypothesis for maternal programming of uterine development, endometrial functionality, and the functional capacity of uterine tissues in the pig.

Maternal Lactocrine Continuum

An abundance of data provide compelling support for the idea that maternal influence over development of offspring extends beyond the womb into neonatal life by consequence of nursing and the transmission of lactocrine signals (Bagnell et al., 2017;

Fig. 1 Developmental programming and lactocrine effects. Maternal effects on offspring development begin at conception and extend through the prenatal period into postnatal life through signals transmitted from mother to nursing young in colostrum (first milk) and mature milk via a lactocrine mechanism. The potential lactocrine signaling window encompasses the period from birth until weaning. The lactocrine programming window, defined as the postnatal period when lactocrine-active factors can affect the organizational programming of somatic cells and tissues with lasting consequences, is likely to be species-specific, and to encompass a shorter period of hours or days from birth. During this period concentrations of potentially lactocrine-active factors in colostrum are highest, and conditions facilitative of delivery of lactocrine-active factors from the neonatal gastrointestinal tract into the circulation are broadly functional. In the pig, lactocrine disruption from birth (PND 0): (i) alters uterine development at cellular and molecular levels by 12 h postnatal; (ii) alters uterine gene expression globally by PND 2; (iii) inhibits endometrial histogenesis by PND 14; (iv) alters adult endometrial gene expression in adults on PxD 13; and (v) reduces functional uterine capacity in adults (See: [Bagnell et al., 2017](#); [Bartol et al., 2017](#)).

[Bartol and Bagnell, 2012](#); [Bartol et al., 2013, 2017](#)). The fact that lactation is a defining characteristic of mammals suggests that lactocrine programming of postnatal development is an evolutionarily conserved, mammalian phenomenon. Data for the pig support the idea of a continuum of events affecting lactocrine signaling and reproductive performance ([Bartol and Bagnell, 2012, 2017](#)). Aspects of this continuum are illustrated in [Fig. 1](#).

During the prenatal period, maternal environmental conditions program fetal and placental development. Factors of maternal and fetoplacental origin define the path of mammary gland development, colostrogenesis and lactogenesis. This determines the potential quantity and quality of colostrum/milk and, therefore, the relative availability and nature of lactocrine signals during the postnatal period. Transmission of lactocrine-active factors from mother to offspring can occur throughout the period from birth to weaning. However, a critical window for lactocrine programming of uterine development is likely open for a short period of time (12–24 h) postnatally ([Fig. 1](#)). For nursing offspring, the relative availability and quality of colostrum determines whether neonates are lactocrine sufficient or lactocrine deficient from birth. This, in turn, affects the uterine developmental program and, ultimately, determines functional uterine capacity in adults. Reduced functional uterine capacity in neonatally lactocrine deficient adults may affect the ability of these animals to support fetoplacental development, thereby affecting mammogenesis, lactogenesis and the nature and quality of lactocrine signals in the next generation. By the same token, lactocrine sufficiency from birth supports optimal postnatal programming of lactocrine-sensitive tissues.

Summary and Conclusions

Nursing and factors delivered to mammalian offspring in colostrum and milk are recognized as essential elements of a continuum of maternal epigenetic contributions to the organizational program that defines developmental trajectory and offspring phenotype. Identification of lactocrine mechanisms regulating postnatal development will aid in understanding the developmental origins of mammalian health and disease. Defining the functional roles and interactions of the immense array of potentially lactocrine-active factors in colostrum and milk ([Table 1](#)) poses a significant challenge that demands to be accepted. Studies are also needed to determine how colostrogenesis, which is programmed maternally during late gestation, affects the nature and quality of lactocrine-active factors found in colostrum. Efforts to identify lactocrine programming mechanisms will contribute to understanding of the postnatal phenome by defining new environmental and epigenetic linkages connecting genotype to phenotype.

Volume 3 of this encyclopedia covers three critical and sequential topics of reproduction: gametogenesis, fertilization, and development. **Gametogenesis** refers to the production of gametes in each sex. This process is markedly different in males and females, involving spermatogenesis and oogenesis, respectively, leading to the production of very distinct gametes: spermatozoa/sperm and oocytes/eggs. Gametogenesis begins with the specification of primordial germ cells in a similar manner in the early embryo in both sexes, followed by the sexually dimorphic processes of spermatogenesis in the male and oogenesis in the female. Although these processes differ phenotypically, they share common features, including the expression of many genes that are not expressed in any other cell types in the body; for example, meiosis, which is unique to germ cells and leads to the production of haploid gametes, and germ line–specific epigenetic reprogramming that erases most inherited epigenetic marks and resets new epigenetic programming to foster gametogenesis and epigenetic inheritance between generations. Processes that differ between spermatogenesis and oogenesis include the ongoing presence of a gametogenic stem cell—the spermatogonial stem cell (SSC) throughout the reproductive life span—in the male, such that adult human males can produce up to 85 million sperm per day, and the absence of any equivalent ongoing presence of a gametogenic stem cell in the female. Rather, in the female, all of the primordial germ cells do not undergo cell death transition briefly to premeiotic oogonia and then to meiotic oocytes that progress to diplotene of the first meiotic division during the fetal period, and then become quiescent until the time of ovulation of each surviving oocyte. The products of gametogenesis—the spermatozoon in the male and the oocyte/ovum in the female—are dramatically dimorphic in terms of morphology, gene expression, epigenetic programming, ongoing signaling pathways, motility, and several other functions that ultimately contribute to the genesis of functional gametes competent to participate in fertilization.

Fertilization is the process by which the male and female haploid gametes become unified to establish the diploid fertilized egg or zygote. This process follows transport of the paternal genome by the sperm from the male reproductive tract to the female reproductive tract, as well as transport of the maternal genome by the oocyte from the ovary into the Fallopian tubes where fertilization takes place. A complex system normally regulates sperm–egg interactions to ensure proper fertilization of the oocyte by a single sperm while simultaneously blocking the ability of all other sperm to fertilize the egg, thus preventing polyspermy. Fertilization marks the point at which individual gametes cease to exist and a new embryo is generated. This process is associated with significant changes in epigenetic programming associated with both the paternal and maternal genomes, plus recruitment of maternally produced mRNAs and proteins to sustain preimplantation development, and activation of the embryonic genome, such that the embryo can initiate development.

Development is the process by which a fertilized egg or zygote grows into a newborn baby in mammals. This begins with preimplantation development—a process that is largely intrinsically regulated within the early embryo on the basis of maternal factors present in the ooplasm, plus new macromolecules generated by gene expression in the early embryo. The initial fertilized egg divides to yield multiple cells in a structure termed a morula, which then continues to grow by cell division and cellular differentiation, as well as cavitation to form the blastocyst. The blastocyst consists of an outer layer of trophoblast cells that will form the extraembryonic structures such as the chorion and the allantois, plus an inner cell mass that will give rise to the embryo proper and, eventually, to the newborn offspring. The zygote is considered to be a totipotent cell because it possesses the potential to form all cell types, including embryonic and extraembryonic cell types. The trophoblast cells rapidly lose this potential, such that they can only form extraembryonic structures, while the inner cell mass are “pluripotent,” meaning they can produce any cell type in the embryo proper.

At the blastocyst stage the embryo implants into the uterine wall, which marks the transition from preimplantation development to postimplantation development. The postimplantation embryo undergoes organogenesis to form the fetus. In the fetus, tissues and organs continue to grow and differentiate so that they can eventually function independently following birth. Each somatic cell lineage develops on the basis of cells sensing their position within the embryo and activating gene expression patterns that will facilitate development of proper structures or organs in proper places within the body. This is associated with unique epigenetic programming and differential gene expression in each.

In addition to all of the somatic cell lineages, the germ line becomes reestablished as the earliest specific cell type allocated within the embryo proper. This marks the beginning of gametogenesis in the new generation, which will start the gametogenesis–fertilization–development cycle over again.

Gametogenesis

As the name implies, gametogenesis refers to the process by which the gametes—oocytes or eggs in females and spermatozoa or sperm in males—are generated. The gametes are the final, differentiated product of the germ line in each sex. However, unlike all other differentiated cells present in the adult, the gametes do not represent terminally differentiated cell types because they participate in fertilization to give rise to an entirely new individual. In this regard, it has been suggested that the germ line is essentially immortal. The gametes are also the only haploid cell type found in the adult. This is because the developing germ cells undergo the process of meiosis which includes one round of DNA replication followed by two rounds of cytokinesis or cellular division. Upon fertilization, the union of the two haploid gametes (sperm + egg) restores diploidy in the zygote.

Development of the Germ Line

The germ line is the first individual cell type allocated during development of the embryo proper. In mammals, the first manifestation of the germ line in each sex is the formation of primordial germ cells (PGCs) at about the stage of gastrulation in the embryo. This process is common to germline development in both the male and female and at this stage the PGCs appear identical in each sex. The PGCs arise in the epiblast and subsequently migrate to the site of the developing genital ridges that will eventually give rise to the gonads. As with the PGCs, the early stages of gonadal development are not significantly different in males and females, although subsequent to this stage both the gonads and the germ cells undergo sexually dimorphic development. The developing gonads are pre-programmed to form ovaries in (XX) females, but expression of the Y-linked *Sry* gene in developing Sertoli cells in the testes in (XY) males induces the indifferent, bipotential gonad to develop into a testis instead of an ovary. Once this gonadal sex differentiation is initiated in the somatic cells of the developing gonads in each sex, the previously indifferent PGCs are induced to initiate sex-specific gametogenesis. Thus, PGCs in a developing ovary are induced to enter the oogenic pathway, whereas those in a developing testis are induced to enter the spermatogenic pathway. It is the sexual phenotype of the somatic elements of the developing gonad that directs the initial choice of which sex-specific gametogenic differentiation pathway the PGCs will enter, regardless of the genetic sex of the PGCs. Normally, genotypically female XX PGCs will be present in a phenotypically female developing ovary and will be induced to initiate oogenesis, whereas genotypically male XY PGCs will be present in a phenotypically male developing testis so will be induced to initiate spermatogenesis. However, even when XY PGCs are present in a developing ovary, they will be induced to initiate oogenesis, just as XX PGCs present in a developing testis will be induced to initiate spermatogenesis. Nevertheless, although the sex-specific somatic phenotype of the developing gonad directs the sex-specific initiation of either oogenesis or spermatogenesis, the ability of the germ cells to complete gametogenesis by forming either functional oocytes or sperm is limited by their sex-specific genotype, such that XY germ cells do not normally produce functional oocytes (though this has been reported on occasion) and XX germ cells never produce functional spermatozoa.

The first manifestation of sexually dimorphic gametogenesis is the entry by oogenic cells into prophase of meiosis I during fetal development while at this same stage spermatogenic cells remain mitotic and do not enter meiosis until well after birth in association with puberty. In both males and females, entry of germ cells into meiosis is stimulated by retinoic acid (RA) produced by gonadal somatic cells. This takes place during the fetal stages in both the developing ovary and the developing testis. However, in the fetal testis, there is also production of an inhibitor of RA (cytochrome P450 26B1 encoded by the *Cyp26b1* gene) which effectively blocks the meiosis-inducing signaling function of RA, and so prevents the induction of entry into meiosis by germ cells in the fetal testis. Prior to and at the time of puberty in the postnatal testis, RA is again produced by somatic cells in the pubertal testis in the absence of any simultaneous production of cytochrome P450 26B1, resulting in induction of entry of spermatogonia into meiosis at this time.

In response to production of RA in the fetal ovary, PGCs enter first meiotic prophase and progress to the diplotene stage. But they then suspend further progression through subsequent phases of meiosis and remain meiotically quiescent until stimulated to resume progression through meiosis upon ovulation in the adult. This prolonged suspension of meiotic progression at the stage when homologous chromosomes have paired on the first meiotic metaphase plate is the source of the marked increase in aneuploid offspring of older mothers due to non-disjunction of the paired homologues.

At the same time when female germ cells are entering into meiosis followed by entry into meiotic quiescence, fetal male germ cells remain mitotic, but also enter a state of mitotic quiescence. This quiescence is more transient than that observed in developing oocytes, lasting only until resumption of expansion of the spermatogonial pool in the immature, postnatal testis.

Nevertheless, it is very intriguing to note that both female and male germ cells enter a stage of quiescence during the latter portion of fetal development. This period of quiescence corresponds to a period of genome-wide epigenetic reprogramming unique to the developing germ line. Whether or not proliferative quiescence is necessary to facilitate germ line-specific epigenetic reprogramming is not known.

Postnatal Gametogenesis

Another striking dimorphism in the manner in which gametogenesis takes place in females and males, respectively, is that the cohort of primary oocytes that develops during the fetal period represents the entirety of the lifelong oogenic pool under normal circumstances in the female. It appears that all of the developing female germ cells enter first meiotic prophase during the fetal period, after which they retain the ability to complete the meiotic divisions, but are not able to further propagate their numbers, thereby limiting the oogenic pool to those primary oocytes that are present at birth. Indeed, many of the early primary oocytes undergo cell death, thus further limiting the pool of oocytes available during the reproductive lifespan of the female. Typically, exhaustion of the primary oocyte pool correlates with menopause in female mammals.

In contrast to the developmental dynamics of oogenesis, the dynamics of spermatogenesis are quite distinct. In the fetal testis, male PGCs develop into prospermatogonia that continue to divide mitotically, thus increasing their numbers significantly. After birth, these mitotically expanded prospermatogonia can either give rise directly to progenitor and/or differentiating spermatogonia, or they can enter a cell death pathway, or, in the case of a small subpopulation of the prospermatogonial pool, they can form spermatogonial stem cells (SSCs). SSCs are unique in that they can either self-renew or proceed through the spermatogenic differentiation pathway. The SSCs are the only cell type in the entire spermatogenic lineage capable of undergoing self-renewal. To accomplish both maintenance of the SSC pool and contribution of cells that will continue through the spermatogenic pathway, the SSCs must undergo, directly or indirectly, an asymmetric division whereby a portion (likely half) of the mitotic progeny of SSCs retain SSC identity and function, while the other portion become committed to entering the spermatogenic pathway. The latter progenitor spermatogonia undergo further mitotic expansion before initiating the spermatogenic pathway as differentiating spermatogonia.

Meiosis

Meiosis is a critical, unique feature of gametogenic cell lineages. Meiosis facilitates multiple beneficial outcomes. Meiotic recombination generates unique rearrangements of the paternal and maternal genomes prior to fertilization. In addition, meiosis achieves a reduction division that yields haploid eggs or sperm that can then re-establish diploidy upon the union of a sperm and egg at fertilization. However, the manner in which meiosis is achieved is also dimorphic during female and male gametogenesis. As noted above, during fetal development in females, all PGCs give rise to oogonia that then proceed into first meiotic prophase. From this stage on, there are no premeiotic (mitotic) female germ cells, and there is therefore no subsequent opportunity to expand the oogenic cell pool beyond completion of the two meiotic divisions. As a result, females possess their entire lifetime supply of germ cells when they are born and this pool will then be steadily reduced by ovulation or cell death throughout the remainder of the female's reproductive lifespan. In contrast, the mitotic SSCs persist throughout the reproductive lifespan of the male and, in addition to sustaining the SSC pool by self-renewal, give rise to progenitors and then differentiating spermatogonia that then progress into meiosis during each succeeding wave of spermatogenesis in the testis.

Albeit on the basis of very different developmental schedules, germ cells progress through the same stages of meiosis in both males and females. This includes an initial round of DNA replication, followed by the various stages of first meiotic prophase (preleptotene, leptotene, zygotene, pachytene, and diplotene) and completion of the first meiotic division as primary oocytes or spermatocytes followed by completion of the second meiotic division as secondary oocytes or spermatocytes prior to formation of the haploid products of meiosis—the ovum in the female and the spermatids in the male. These steps occur as distinct stages during spermatogenesis as cells progress from premeiotic spermatogonia to meiotic primary spermatocytes and then secondary spermatocytes to postmeiotic round and then elongating spermatids to spermatozoa. During oogenesis, these steps occur in rapid succession following resumption of first meiotic prophase in the female, and are triggered by ovulation and fertilization.

Postmeiotic Gametogenesis

The completion of the first and second meiotic divisions is very disproportionate in oocytes, yielding the very small first and second polar bodies while leaving the large majority of the ooplasm intact in the ovum. Thus, only one of the four products of female meiosis yields a functional gamete, but that one gamete will contain abundant maternal nutrients and factors that will sustain preimplantation embryogenesis following fertilization. In the male, all four products of meiosis emerge as round spermatids that then undergo the differentiative process of spermiogenesis to progress from small, round haploid cells to elongating spermatids and finally to the highly differentiated spermatozoa, all in the absence of any further cellular division. The resulting testicular spermatozoa are then released from the seminiferous epithelium by the process of spermiation and are then transported through the lumen of the seminiferous tubule to the rete testis which serves as a collection area prior to transport of spermatozoa out of the testis and into the epididymis via the efferent ducts. The spermatozoa then traverse the various sections of the epididymis, including the caput, corpus, and cauda regions before moving into the vas deferens from where they are available for release from the male via ejaculation. Transit of the testicular spermatozoa through the epididymis is critical to the acquisition of motility and fertility, yielding mature spermatozoa competent to participate in fertilization.

The Gametogenic Transcriptomes

Unique patterns of gene expression are required to facilitate the unique gametogenic processes of oogenesis and spermatogenesis. Because the gametes are, in many ways, distinct from any of the somatic cell types, there are numerous oogenesis- or spermatogenesis-specific members of gene families, and/or variants of mRNAs (e.g., splicing variants) or proteins (e.g., post-translational modifications). The transcriptomes associated with oogenesis and spermatogenesis are highly complex and largely unique, rivaled only by the brain in these respects. Coordination of expression of these unique transcriptomes is facilitated by many gametogenesis-specific regulatory factors including oogenesis- or spermatogenesis-specific transcription factors, chromatin remodeling factors, and components of other regulatory networks.

Germline-Specific Epigenetic Reprogramming During Gametogenesis

In addition to undergoing meiosis common to both oogenesis and spermatogenesis, as well as the sex-specific differentiation patterns associated with oogenesis or spermatogenesis to yield the egg (ovum) or spermatozoon (sperm), respectively, the germ cells also undergo a unique process of epigenetic reprogramming coincident with the process of gametogenesis in each sex. As noted above, germ cells are unique in that they undergo extensive differentiation to yield the male and female gametes, but these gametes then participate in fertilization to give rise to a complete new individual in which all cell types will subsequently re-emerge. Thus, distinct regulatory mechanisms are required to (1) direct the gametogenic differentiation processes and (2) prepare the gametogenic genomes to contribute to development of the embryo following fertilization. This is achieved by reprogramming of the epigenome in both the preimplantation embryo and the developing germ lines.

Embryonic reprogramming is achieved by erasing a majority of the epigenetic programming that is inherited via the gametes at the time of fertilization. This is followed by resetting of epigenetic programming that is common to the precursors of both somatic and germline cells and is complete by the time of gastrulation in the developing embryo. Subsequently, all somatic cell lineages retain the majority of this reset epigenetic programming. However, a second round of germline-specific epigenetic programming is initiated in the PGCs in which extant epigenetic programming is once again erased—to an even greater extent than the erasure that occurs in the preimplantation embryo, and this is followed by yet another round of resetting of epigenetic programming that follows distinct patterns in oogenic and spermatogenic cells, respectively. This germline-specific epigenetic reprogramming facilitates the processes of gametogenesis in both sexes, including meiosis and either oogenesis or spermatogenesis, as well as the preparation of the gametogenic genomes to direct subsequent early embryonic development following fertilization.

Maintenance of Enhanced Genetic Integrity During Gametogenesis

A critical function of the germ line that must be maintained during gametogenesis in each sex is the integrity of the gametogenic genomes, such that the genetic information transmitted from one generation to the next is preserved in an optimally pristine state. While a relatively small amount of genetic variation among individuals and between generations is beneficial, most spontaneous or induced genetic variation is not advantageous. Therefore it is not surprising that genetic integrity is maintained more stringently and faithfully in the germ line than in any somatic cell lineage. This is achieved by elevated levels of expression and corresponding activity of multiple cell death and DNA repair pathways. The former are typically induced in response to the occurrence of large scale genetic defects or damage such as polyploidy, aneuploidy, major chromosomal rearrangements or extensive DNA damage genome wide, thus dealing with these defects retrospectively. However, more minor genetic defects such as point mutations which are the most common disease-related genetic defects do not typically induce cell death and can only be minimized by prospectively preventing their occurrence. Enhanced DNA repair activities serve to reduce the initial occurrence of point mutations by increasing the likelihood that initial DNA damage will be corrected prior to becoming stabilized as a heritable point mutation. These elevated levels of cell death and DNA repair activities exemplify a situation in which a long-term evolutionary benefit offsets the evolutionary expense of the elevated investment of additional energy required to achieve the beneficial outcome.

Introduction and History of Meiosis

Meiosis is the specialized cell division process that takes a diploid precursor cell and from it generates up to four haploid cells for sexual reproduction in eukaryotes. In mammals, the haploid products of meiosis are referred to as gametes: the spermatozoa of males, and the oocytes (or eggs) of females. Meiosis differs from the mitotic cell division in many respects, most notably in that it is comprised of two divisions preceded by only a single phase of DNA replication. While many other differences exist, much of the generalized mitotic machinery is conserved in meiosis, and this conservation is also apparent across organisms and between sexes.

Meiosis was first observed in sea urchin eggs in 1876 by German biologist, Oscar Hertwig. A decade later, Belgian zoologist, Edouard Van Beneden, described a similar process in the eggs of the roundworm, *Ascaris*. It was not until the 1890s, however, that August Weismann noted the importance of the two cellular division events for generation of haploid gametes for fertilization. The term *meiosis*, derived from the Greek word for “lessening” was coined in 1905 by Farmer and Moore to reflect the halving of the chromosomes. These early observations preceded the rediscovery of Mendel’s work by Hugo de Vries and others in the 1900s, and culminated in 1911 with the discovery by Thomas Hunt Morgan of crossing over, the exchange of genetic information between homologous chromosomes as a result of recombination, a key and essential feature of meiosis.

In order to derive haploid daughter cells following a single round of DNA replication, meiosis consists of two distinct segregation events: meiosis I and meiosis II. Both meiotic divisions consist of prophase, metaphase, anaphase, and telophase (Fig. 1), but whereas the first division is considered equational (maintaining the number of genome copies, or ploidy, of the daughter cells), the second is reductional (halving the ploidy of the daughter cells), and thus very similar to mitosis. During meiosis I, homologous chromosomes, derived from each parent (maternal and paternal), must first find each other and pair, in order to then be segregated equally into two daughter cells. Like mitosis, meiosis II involves separation of sister chromatids, which are connected through their cohesin rings, the protein complexes that maintain sister chromatid interactions through the cell cycle. These sister chromatids are segregated to opposite poles prior to cytokinesis, resulting in the halving of the genome content. The fact that sister chromatids are already paired makes mitosis and meiosis II fairly easy to orchestrate: a simple separation of the chromatids following dissolution of the cohesin ring. For meiosis I, however, the homologous chromosomes are not usually tethered together, and thus, they must undergo a fascinating, and relatively poorly understood process of homology searching, pairing and then physical tethering, in order to allow them to be segregated equally at the first meiotic division. Thus, it is meiosis I, involving homologous chromosome interactions, that represents the unique and defining phase of meiosis.

General Scheme of Meiotic Progression in Eukaryotes

While differences exist across species in the functional regulation of meiosis, the staging and progression of meiotic events follows a generally similar pattern as that of mammals, described here for male mammals, with particular emphasis on what is known in the laboratory mouse. Following a set and species-specific number of mitotic divisions, the spermatogonia of the adult testis are triggered to enter meiosis predominantly through the actions of retinoic acid (RA). RA-responsive genes, including *STRA8*, promote premeiotic S-phase, which doubles the genetic content of the cell. These cells are now known as 2N, because they contain two copies of every chromosome, and 4C, because they contain a total of four sister chromatids (or four copies of the genome). These cells then enter prophase I of meiosis, which is by far the longest stage, lasting up to 10 days in male mice. Prophase I can be further subdivided into five distinct substages (Fig. 2): *Leptonema* (adjective: leptotene), *Zygonema* (adjective: zygotene), *Pachynema* (adjective: pachytene), *Diplonema* (adjective: diplotene), and *Diakinesis*. During these stages, homologous chromosomes, each consisting of paired sister chromatids must first find each other, pair, and then undergo a physical tethering process known as *synapsis*. This tethering is achieved by the accumulation of a set of proteins that comprise a scaffold structure along and between homologous chromosomes that are known collectively as the *synaptonemal complex* (SC). The sequential accumulation of the SC defines the substages of Prophase I and goes hand-in-hand with the second defining feature of this stage: *meiotic homologous recombination* (HR). Meiotic recombination results in the formation of crossovers, which are regions of exchanged chromosome length between the parental chromosomes. The cytological manifestation of crossing over are the *chiasmata*, and these serve to tether homologous chromosomes together until the first meiotic division. SC formation and HR are intricately intertwined events, the latter being initiated first and seeding the formation of the former (see below).

Fig. 1 Overview of mammalian meiosis. A representative cell is shown containing two pairs of homologous chromosomes (red/pink and green/yellow). At interphase, these cells are diploid, containing 2n and 2c content. “n” refers to the number of homologous chromosomes and “c” refers to the number of chromatids and/or the number of copies of each gene locus. After DNA replication, therefore, the cell is still 2n, but is now 4c (four copies of each chromatid, two for each chromosome). After the first meiotic division, when homologous chromosomes have divided, the daughter cells (one secondary spermatocytes or one secondary oocyte) are now 1n, 2c, containing only one homologous chromosome, but two sister chromatids. By the end of the second division, this chromosome content is reduced further to 1n, 1c. Note that only one cell emerges at the end of meiosis in females, the remaining genetic content being expelled in the first and second polar bodies. Modified from Chapter 1, *Physiology of Reproduction*, eds. Knobil and Neil (2013).

The outcome of prophase I is the tethering of homologous chromosomes, firstly through SC-mediated protein:protein interactions and then through HR-mediated DNA:DNA interactions, the latter which much then be appropriately processed and distributed to result in a precisely determined cohort of chiasmata. These chiasmata persist into metaphase I when, in conjunction with the cohesin rings which encircle the sister chromatids across their entire lengths, they allow for accurate tension to be established on the meiosis I spindle. This tension is crucial for ensuring that homologs segregate equally to opposite poles of the cell at anaphase I. Homolog segregation is facilitated by the resolution of chiasmata to form intact and appropriately recombined homologous chromosomes, as well as by the specific release of cohesion along chromosome arms, but not at the centromere. The maintenance of centromere cohesion at the first meiotic division ensures that sister chromatids remain together through until meiosis II.

The segregation of homologous chromosomes at the first meiotic division results in two daughter cells that are each now 2C and N in terms of genomic content, containing one of each chromosome, with each chromosome consisting of two sister chromatids (or two copies of the genome, hence the “equational” division). Each of these cells will undergo a mitosis-style division, culminating in segregation into two daughter cells each (for a total of four daughter cells). These final products, termed *gametes* in mammals, or *meiospores* in fungi/plants, are now 1C (one copy of the genome) and 1N (one chromosome) in total genomic content, the haploid products of a reductional division. In males, these gametes will now enter the postmeiotic differentiation stages of spermatogenesis as newly-formed spermatids.

Fig. 2 Overview of prophase I and alignment of the events of synapsis (left) with that of recombination (right). Synapsis is depicted in cartoon form (left) and with representative fluorescence micrographs (right) showing mouse spermatocytes in prophase I. The SC lateral element protein, SYCP3 is shown in red, and the central element protein, SYCP1, in green, at each of the first four stages of prophase I. The last stage, diakinesis, is not shown because SC proteins are no longer present at this time. Note that the staining depicts proteins only; the DNA is distributed throughout the field as loops emanating away from the SC structure. The right panel depicts DSB formation and repair through one of several pathways. At least two pathways give rise to non-crossovers (SDSA and Dissolution), and at least two pathways give rise to crossovers (Class I and Class II) and the approximate timing of the appearance of these products is related to the vertical scale of prophase I stages on the left. Modified from Gray and Cohen, *Annual Review of Genetics* (2016).

Female meiosis follows a similar profile to that of males, but with several exceptions. Most notably, meiosis occurs in a synchronous fashion amongst all oocytes during embryonic development (described later). Additionally, at meiosis I when the primary oocyte has divided, only one set of homologous chromosomes become encapsulated in a secondary oocyte. The remaining chromosomes are discarded in a polar body that degenerates over several hours. At the second meiotic division, when sister chromatids are segregated, again only one set of sister chromatids become encapsulated in the final oocyte, and the remaining genetic material is again expelled as the second polar body. Thus, female meiosis results in the production of only one oocyte.

Regulation of Prophase I Events: Meiotic Homologous Recombination

As described above, Prophase I is the defining feature of meiosis and by far the longest phase. Upon entry into leptonema, homologous chromosomes are long and uncompacted and must first initiate meiotic HR and undergo the intricate and poorly understood process of homology recognition and pairing. The first key event in leptonema, therefore, is the induction of hundreds of DNA double strand break (DSB) across the genome, mediated by the topoisomerase VI subunit A-like protein, SPO11, in conjunction with its recently-identified B-type subunit, TopoVIB-like (TOPOVIBL) (Keeney et al., 1997; Grelon, 2016). Together, SPO11 and TOPOVIBL act with several co-factors to induce DSB formation at hundreds of sites across the genome, with some 250 DSBs formed in mouse meiosis, and over 600 DSBs formed during human meiosis. Of these, only 10% will become the crossovers (CO) that are needed to ensure homologous chromosome interactions, while the remaining DSBs will be processed as noncrossovers (NCO) in which flanking DNA sequence is not exchanged between homologs, and thus will not promote interhomolog connections (Fig. 2).

Importantly, all of the DSBs must be repaired in an accurate and temporally defined manner, both to ensure the correct distribution of COs across the genome, but also to prevent incurring a DNA lesion in the resulting gamete.

Regardless of the final outcome of DSB formation (CO or NCO), DSB events are processed in a similar fashion for the early events of DSB repair (Hunter, 2015). The DSB becomes resected to form 3' overhangs on either side of the DSB and these become stabilized by replication protein A (RPA). Two distinct RecA homologs, RAD51 and meiosis-specific DMC1, then associate with the overhang and these proteins promote strand invasion, also known as *single end invasion*, into closely apposed chromosomes. In doing so, RAD51 and DMC1 promote strand displacement in the opposing chromosome, and thereby mediate a homology search process that culminates with the complete pairing of homologous chromosomes by late zygonema/early pachynema. Thus, regardless of the outcome of the DSB repair process, the induction of many DSBs is thought to be critical for homology searching and recognition.

Following single end invasion, the major repair pathway is thought to result exclusively in NCO events, and may involve up to 90% of the original DSBs. This pathway, known as *synthesis-dependent strand annealing* (SDSA), and involves first extension, and then rejection of the invading DNA strand, followed by reengagement/annealing with the original opposing end of the DSB (McMahill et al., 2007). Following further DNA synthesis to repair all the gaps in the strand caused by the original DSB processing, the resulting repair is now termed an NCO because of the lack of exchange of flanking DNA sequence between DNA strands.

As an alternative to SDSA, following single end invasion, the free end of the single strand is captured at the other side of the DSB, resulting in a D-loop structure that can be processed in multiple ways, depending on the DNA repair pathway that is invoked. In terms of COs, the major pathway is the ZMM pathway (or Class I pathway), named for the proteins that regulate these events in budding yeast (Fig. 2). These include the DNA mismatch repair proteins, MutS homologs-4 and -5 (MSH4 and MSH5), collectively termed MutS γ , which associate with a subset of DSB repair events, driving them towards a CO fate. Importantly in mammals, however, not all of the MutS γ -defined intermediates become COs since the number of MSH4 or MSH5 foci found on the chromosomes is considerably higher than the final tally of COs, suggesting that a cohort of these intermediates is destined to become NCO events (Kneitz et al., 2000). The current understanding is that these CO-destined MutS γ sites are stabilized progressively by proteins that invoke posttranslational modifications. These so-called CO-licensing factors may include the SUMO E3 ligase, RNF212 (Reynolds et al., 2013). Final *crossover designation* is achieved by the accumulation of the DNA mismatch repair heterodimer of MLH1 and MLH3, collectively termed MutL γ , which associates with only those MutS γ sites that will become COs (Lipkin et al., 2002; Edelmann et al., 1996). Crossover designation is orchestrated by other factors, including the cyclin family member, cyclin N-terminal domain containing-1, CNTD1, and by the Ubiquitin E3 ligase, Human Enhancer of Invasion-10, HEI10 (Qiao et al., 2014; Holloway et al., 2014).

As alluded to above, the distribution of COs (and therefore, also of NCOs) must be tightly regulated during prophase I to conform to several rules. Firstly, *crossover assurance* is the process by which an *obligate crossover* is present on every chromosome, ensuring accurate homolog engagement through until the first meiotic division. Secondly, the placement of one CO reduces the likelihood of a second nearby chromosome, in a process called *crossover interference*, ensuring that no one stretch of chromosome receives too many or too few COs. Finally, in a process termed *crossover homeostasis*, the number of DSBs can be reduced many fold at the expense of NCOs, while COs are retained at their optimal level. Thus CO regulation encompasses all of these requirements and must be orchestrated within the complex DSB repair mechanisms that also ensure complete repair of the entire DSB cohort through prophase I.

Regulation of Prophase I Events: Synaptonemal Complex Formation

Concurrent with DSB induction is the onset of synapsis, in which the synaptonemal complex (SC) progressively tethers the two homologous chromosomes together (Cahoon and Hawley, 2016) (Fig. 2). The synaptonemal complex was first visualized by Moses and Fawcett in 1956, and consists of two axial/lateral elements that align each homolog and the central element that resides between the two homologs. Transverse filaments, which have one end anchored in the lateral element and the other in the central element, function to “zip” the two homologs together during early prophase I, in the process that is intricately linked to the homologous recombination events taking place concurrently with synapsis. In mouse and other organisms, DSB induction precedes SC assembly while in *Drosophila melanogaster*, SC assembly initiates in advance of DSB formation (McKim et al., 1998). In the former, it has been postulated that DSB repair creates single stranded overhangs that are required to initiate homolog interactions leading to synapsis, perhaps explaining why so many more DSBs are generated than are actually required for crossing over. Interestingly, though most meiotic species exhibit synapsis (there are exceptions to this rule), and while the overall structure of the SC is conserved, the proteins that comprise the SC vary quite markedly. This suggests that different organisms have evolved distinct mechanisms to create the same structure.

In mice, the initiation of synapsis is dependent on the 250–300 DSBs that form, such that, any reduction in DSB formation leads to delayed SC assembly. The importance of the SC in mouse is demonstrated by the fact that loss of one or more SC proteins, such as the axial element protein SYCP3, or the central element protein, SYCP1, leads to prophase I disruption (Yuan et al., 2000, 2002). Other proteins also participate in this process, including the HORMA-domain containing proteins, HORMAD1 and HORMAD2 (Wojtasz et al., 2009; Shin et al., 2010). These two proteins associate exclusively with unsynapsed axes, and their presence is essential for normal DSB repair, resulting in an inextricable co-dependence between synapsis and homologous recombination (Shin et al., 2010; Fukuda et al., 2010).

The First Meiotic Division

Upon completion of prophase I, the SC has broken down, and crossing over has taken place. Upon entry into metaphase I, the homologous chromosome pairs line up along the mid-plate of the cell, the orientation of maternal/paternal chromosomes toward each pole being random. Homologous chromosomes must attach to the spindle in a bi-orientated manner to ensure that homologous chromosomes separate, while sister chromatids adopt a co-orientation to ensure that they remain together. Thus, unlike mitosis and the second meiotic division (MII), where the kinetochores of the sister chromatids undergo *amphitelic attachment* to the bipolar spindle (attaching to opposing poles of the spindle, thus called *bi-polar* attachment) to ensure equal segregation thereof, during the first meiotic division (MI), the kinetochores of the sister chromatids must attach in a *syntelic* fashion (attaching to the same pole, called *mono-polar attachment*) in order to ensure that they segregate together to the same pole.

At MI, bi-orientation of homologs is achieved by a combination of the presence of cohesin rings along the arms of the chromosomes and at the centromeres, together with the physical exchange of DNA at the CO sites. In this respect, it is not the CO alone that is important, but the overall tension achieved by the interlocked homologs that have exchanged DNA sections but which still retain the original cohesin complexes that exist along each homologous chromosome.

Cohesin removal at metaphase I is distinct from that of mitotic metaphase in the requirement for a specific sequential loss of cohesion along chromosome arms the first meiotic division (MI) followed by loss of centromeric cohesion at the second meiotic division (MII). The loss of cohesins along chromosome arms is necessary to achieve accurate segregation of the newly-recombined homologous chromosomes. However, in order to maintain sister chromatid interactions through until the second meiotic division, it is necessary to facilitate the retention of cohesin complexes at the centromere. Thus, at MI, arm cohesion is lost through two distinct mechanisms. Firstly, a nonenzymatic *Prophase I* pathway involving the Wings Apart-Like protein, WAPL, promotes opening of the cohesin ring at part of a phosphorylation cascade involving NIMA-like kinase-1 (NEK1) and protein phosphatase-1 γ (PPI γ) (Bri  o-Enr  quez et al., 2016). As a second mechanism, the phosphorylation of the kleisin subunit of the cohesin ring, REC8, leads to its subsequent cleavage by the enzyme, Separase, but only after the latter has been released by its negative regulator, securin (Fig. 3). Meanwhile, centromeric REC8 is protected from the actions of Separase by the recruitment of phosphatase 2A (PP2A) to the centromere by Shugoshins 1 and 2 (SGO1/2). PP2A prevents Separase-mediated cleavage of the cohesin ring by dephosphorylation of REC8.

The bi-polar orientation of homologs at MI and of sister chromatids at MII, establishes tension across the entire spindle structure that is critical, not only for accurate segregation, but also as a sensing mechanism to ensure that the conditions are met to facilitate the metaphase-to-anaphase transition. This so-called *spindle assembly checkpoint* (SAC) monitors bi-polar attachment and prevents further progression of the cell cycle until stable kinetochore attachment to the spindle. Once these conditions have been met, release of the SAC allows for the activation of the *anaphase promoting complex/cyclosome* (APC/C) and binding to CDC20 (Fig. 3). APC/C, an ubiquitin E3 ligase, targets several proteins for destruction through polyubiquitylation, including

Fig. 3 The spindle assembly checkpoint and progression through the first meiotic division. Cartoon depiction linking SAC activation and monitoring to chromosome segregation at MI. Modified from Chapter 1, *Physiology of Reproduction*, eds. Knobil and Neil (2013).

the Cyclin B component of *maturation promoting factor* (MPF), and Securin. Destruction of Securin, in turn releases the enzyme Separase, allowing the latter to cleave REC8 specifically along the chromosome arms. This elegant system, therefore, allows for the timely destruction of cohesin along chromosome arms only once bi-orientation of homologs, and appropriate spindle tension, is assured. It should be noted that the importance and functionality of the SAC in male MI is unclear currently, while in females, the MI checkpoint is somewhat more permissive, allowing a few unattached kinetochores to evade the SAC arrest (Gui and Homer, 2012).

The Second Meiotic Division

The second meiotic division, or MII, is very similar to the mitotic divisions, involving the amphitelic attachment of sister kinetochores to the spindle. The actions of Separase are no longer restricted at the centromere through mechanisms that remain unclear. In mammals, two Shugoshin proteins exist, SGO1 and SGO2. While SGO2 appears to redistribute prometaphase II in mouse oocytes in a manner that is dependent on microtubule attachment of kinetochores, SGO1 and PP2A persist at the centromere. This retention of PP2A suggests that other mechanism must allow for Separase-mediated REC8 cleavage. Instead, it has been proposed that PP2A is inactivated by other mechanisms during MII, at least in female mammals (Miller et al., 2013).

Female Meiosis is Punctuated by Arrest Periods

While the general scheme of meiosis is similar across sexually reproducing organisms, there are some distinct differences between species and, in mammals, between sexes. In males, meiosis initiates postnatally and, most often, postpubertally, proceeding in waves across the seminiferous tubules of the testis. Self-renewing spermatogonial stem cells proliferate as spermatogonia and then enter meiosis sequentially, with cohorts of spermatogonia embarking on meiosis throughout the life of the individual. In female mammals, meiosis initiates synchronously, or semisynchronously, amongst the entire population of oogonia, such that prophase I is completed during gestational life. Toward the end of prophase I, instead of progressing through to metaphase I, cells enter an arrest period known as *dictyate arrest*. During this arrest phase, homologous chromosome interactions remain intact, manifested by the persistence of the cohesin rings along chromosome arms and the chiasmata. These *bivalent* chromosomes persist through dictyate arrest until after puberty, when cohorts of oocytes are triggered to resume meiosis with each estrus/menstrual cycle. Thus, in species such as humans, chiasmate-intact bivalents must persist for up to several decades before resuming meiosis.

Meiotic resumption in most mammals is triggered by the surge in pituitary-derived luteinizing hormone (LH) that also triggers ovulation (Fig. 4). Under conditions of dictyate arrest, oocyte meiosis remains arrested by the persistent phosphorylation and inactivation of MPF, which consists of cyclin B and its cyclin-dependent kinase partner, CDK1. Phosphorylation of CDK1 by

Fig. 4 Maintenance of dictyate arrest and resumption of the first meiotic division. Purple depicts events in the oocyte, and green depicts events in the neighboring granulosa cells. Dictyate arrest is maintained by keep maturation promoting factor (MPF) phosphorylated (by WEE1 kinase). This is achieved through the activity of protein kinase A (PKA) that is activated by high cAMP levels in the oocyte. Orange depicts LH stimulated events at ovulation, all of which culminate in the activation of MPF through dephosphorylation by CDC25B by removing PKA. Modified from Chapter 1, *Physiology of Reproduction*, eds. Knobil and Neil (2013).

WEE1 is promoted by high levels of cyclic AMP (cAMP) in the oocyte which, in turn, activates Protein Kinase A (PKA) to phosphorylate (and activate) WEE1. Simultaneously, PKA suppresses the activity of CDC25B, the phosphatase that dephosphorylates CDK1. cAMP is maintained at high levels through dictyate arrest by multiple mechanisms that are intrinsic to the oocyte, as well as by extrinsic factors from neighboring granulosa cells. At the time of the LH surge, LH reduces cAMP and PKA levels in the oocyte by suppressing granulosa cell-stimulated cAMP-promoting factors, by enhancing the inhibitory effect of Phosphodiesterase 3A (PDE3A) on cAMP, and by sequestering PKA in the mitochondria. All these events serve to reduce WEE1 and CDC25B phosphorylation, resulting in a dephosphorylation of MPF. This newly activated MPF then drives the resumption of meiosis, allowing completion of prophase I and entry into MI. However, as described above, MPF is then rapidly degraded by APC/C following bi-orientation of homologous chromosomes on the microtubular spindle, allowing for the metaphase-to-anaphase transition. Thus, resumption of meiosis I from dictyate arrest is achieved through the stepwise activation of MPF through dephosphorylation, followed by CDC20-mediated APC/C activation and subsequent degradation of MPF, co-incident with Separase-mediated release of chromosome arm cohesion.

Resumption of MI is followed by rapid progression into meiosis II, up until metaphase II, during which time MPF levels reaccumulate, and the oocyte once again arrests in anticipation of fertilization. This second arrest is maintained by *cytostatic factor*, the major components of which are c-Mos and EMI2 (Masui and Markert, 1971; Sagata et al., 1989). EMI2 is an inhibitor of APC/C, thereby preventing a second round of ubiquitylation and degradation of MPF. Thus arrest is maintained until fertilization, when sperm-egg fusion leads to the release into the oocyte cytoplasm of a sperm-derived phospholipase-C isoform, PLC-zeta (PLC ζ ; Fig. 5) (Saunders et al., 2002). PLC ζ induces increases in intracellular calcium that ultimately lead to upregulation and activation of two kinases: calmodulin-dependent protein kinase II (CaMKII) and Polo-like kinase (Plx1). These two kinases act sequentially to phosphorylate EMI2, leading to the proteolytic destruction of CSF and releasing APC/C inhibition. This now allows APC/C to target MPF for destruction, and permits MII resumption.

Human Meiosis is Error Prone

Aneuploidy is the presence of an abnormal number of chromosomes and is highly prevalent in human gametes. Indeed, aneuploidy is the leading genetic cause of spontaneous miscarriage and congenital birth defects in our species. The reported incidence of aneuploidy in human gametes and embryos varies widely, with approximately 4% aneuploidy incidence in stillbirths, 35% aneuploidy incidence in spontaneous miscarriages, and up to 70% aneuploidy incidence in eggs or polar bodies from assisted fertility clinics (Nagaoka et al., 2012). Regardless of the true incidence in humans, two clear facts remain uncontested: that the majority of aneuploidy errors are the result of maternal meiosis, with maternal age being a strong contributing component, and that the rates of aneuploidy in humans is staggeringly high compared to other meiotic species.

Fig. 5 Resumption of the second meiotic division in mice. The second meiotic arrest is maintained by high levels of cytostatic factor (CSF), consisting of MOS and EMI2. Upon sperm-egg fusion, the release of sperm-derived phospholipase C zeta into the oocyte cytoplasm leads to increases in intracellular calcium, that initiates various events, including meiotic resumption. Increased calcium activates two kinases, CaMKII and Plx1, which together phosphorylate EMI2, thereby leading to the proteolytic destruction of CSF. This releases the inhibition of APC/C by CSF, allowing the former to now degrade MPF (cyclin B-CDK) through ubiquitylation. Loss of MPF leads to meiotic resumption. Modified from Chapter 1, *Physiology of Reproduction*, eds. Knobil and Neil (2013).

The causes of the high incidence of aneuploidy in humans are likely to be varied and complex. That maternal age is a contributing factor underscores the fact that the protracted dictyate arrest observed in women may predispose eggs from older women to errors and/or inappropriate segregation at the first meiotic division. This is supported by observations demonstrating that age-related loss of meiosis-specific cohesin components can lead to increased aneuploidy in mice (Chiang et al., 2010). However, maternal age is certainly not the only cause of aneuploidy in humans, since oocytes from ovaries of human XX fetuses show substantial variation in DSB repair events, and CO processing, as defined by the localization of MLH1 foci during prophase I (Lenzi et al., 2005). Thus DSB repair processing and/or inefficient CO formation are likely to play key roles in ensuring appropriate chromosome segregation at MI. Moreover, it is likely that differences exist between male and female meiosis in the maturation of DSB repair sites to become COs, whereby female meiosis exhibits a more inefficient and error prone CO placement and maturation than observed in male meiosis (Wang et al., 2017). Other sex-specific differences are likely to exist, particularly in the checkpoint mechanisms that sense errors in DSB repair and/or synapsis, and that these differences between the sexes account for different error rates in male versus female meiosis. Indeed, mutant mouse models that exhibit synaptic defects display apoptosis of male spermatocytes, whereas some oocytes can survive these defects, suggesting that errors in prophase I progression can be better tolerated in females than in males.

Whether deficits in meiotic processes during human fetal development arise from genetic errors, in key DSB repair genes for example, or whether they are environmental/toxicological in nature remain to be seen. Almost certainly, genetic factors exist, as evidenced by the numerous polymorphisms in DSB repair genes that associate with infertility. In addition, however, environmental toxins, such as bisphenol A, have also been implicated since these estrogenic chemicals can cross the placenta and have dramatic effects on meiotic events in the fetal ovary (Hunt et al., 2012). More recently, it has emerged that meiotic recombination errors are more prevalent in the sperm of adolescent boys than in older men (Zelazowski et al., 2017) suggesting that some requirement for endocrine maturation of the hypothalamic-pituitary-gonadal axis may be important for supporting proper meiotic progression in mammals.

Glossary

Acrosome A Golgi derived organelle that forms over the nucleus to become a membrane-bound vesicle containing dense granules; contains hydrolytic enzymes necessary for the acrosome reaction at fertilization.

Cycle A complete sequential progression of the cellular associations (or stages) that occur in the formation of spermatozoa that occur over time is called a cycle of the seminiferous epithelium.

Seminiferous epithelium Consists of two cell types, a Sertoli cell, and male germ cells at various steps of development.

Sertoli cell The somatic cells of the testis that are essential for testis formation and spermatogenesis. Sertoli cells facilitate the progression of germ cells to spermatozoa via direct contact and by controlling the environment milieu within the seminiferous tubules.

Spermiation A complex process by which spermatozoa are released into the seminiferous tubule lumen after detaching from the Sertoli cell junctional complex.

Stages A stage (numbered with Roman numerals) is represented by a defined association of spermatogonia, spermatocytes, spermatids in a cross section of seminiferous epithelium, at a specific phase in time during spermatogenesis. The acrosomal system is commonly used to identify specific stages in the cycle of the seminiferous epithelium.

Stem cell Spermatogonial stem cells (SSCs) are a subtype of undifferentiated spermatogonia that both self renew or differentiate to undergo the stages of spermatogenesis.

Introduction to Spermatogenesis

The mammalian testis is comprised of two major compartments: the interstitium, within which the testosterone-producing Leydig cells and the testicular vasculature reside, and the seminiferous tubules, which contain the somatic Sertoli cells and the developing germ cells with which the Sertoli cells associate ([Fig. 1](#)). Spermatogenesis begins with diploid spermatogonial stem cells that mitotically divide to become spermatocytes, followed by two meiotic divisions resulting in haploid round spermatids, and then the differentiation of the spermatids during spermiogenesis to form mature spermatozoa ([Fig. 2](#)). The mature spermatozoa then enter the epididymis where they develop into spermatozoa with the ability for forward motility and fertility. Germ cell divisions and differentiation occur in association with the Sertoli cells. The Sertoli cells produce proteins that are required for spermatogenesis and, in turn, are themselves regulated in part by changes in the developing germ cells with which they are associated. The complex interactions between the Sertoli cells and the surrounding germ cells are crucial for spermatogenesis ([Russell et al., 1983](#)).

Sertoli Cells

Sertoli cells extend from the basement membrane of the tubules to the tubule lumen ([Figs. 2 and 3](#); [Russell et al., 1983](#); [Russell and Tallon-Doran, 1983](#)). Spermatogonial cell divisions occur in the basal compartment of the seminiferous tubules, between the tubule basement membrane and the tight junctions between adjacent Sertoli cells. As the germ cells enter meiosis as primary spermatocytes, they move from the basal to the adluminal compartment of the testis, with tight junctions reforming beneath them. Meiosis involves pairing of homologous chromosomes and crossing over/genetic recombination between the pairs. This results in the production of haploid secondary spermatocytes with genetic compositions that differ from one another and from the cells from which they derive. The secondary spermatocytes and cells derived from them (spermatids) express unique surface antigens and thus require protection from the immune system. Sertoli–Sertoli tight junctions form the blood–testis barrier, which helps to protect the meiotic and subsequent developing germ cells from the immune system and from potentially harmful blood-borne chemicals ([Franca et al., 2016](#)).

Phases of Spermatogenesis

Spermatogonial Proliferation

The continuous production of spermatozoa, and thus male fertility, requires the maintenance of a pool of stem spermatogonial cells (SSCs) and the regulated differentiation of a subset of these cells ([Fig. 4](#)) ([de Rooij, 2017](#)). The SSCs are single cells (A_s) that encode

Fig. 1 Depiction of transition steps from round spermatid to elongated spermatozoan.

subunits of the glial cell line-derived neurotrophic factor (GDNF) receptor Ret and GFR α 1, as well as the transcription factor PLZF. The SSCs do not express Kit, which is expressed by more mature, differentiating spermatogonia. SSCs are scarce; in mice, there are approximately 30,000/testis. In culture or after injection into a blastocyst, the stem cells are able to give rise to cells of ectodermal, mesodermal and endodermal lineages, indicating that they are pluripotent. Divisions and subsequent differentiation of the SSCs are regulated at least in part by factors derived from their surroundings (their niche). The niche is created in part by the Sertoli cells which secrete glial cell line-derived neurotrophic factor (GDNF) as well as other growth factors that are involved in regulating SSC function. Analyses of transgenic mice have shown that GDNF is involved in the suppression of SSC differentiation and thus in maintaining populations of SSCs. In contrast, inhibition of GDNF signaling reduces the self-renewing replication of the SSCs, thus allowing their differentiation to form progenitor spermatogonia. The progenitor spermatogonia replicate to give rise to fully

Fig. 2 Formation of Manchette during spermiogenesis.

Fig. 3 Drawing of reconstructed rat Sertoli cell. The cell is columnar, with the base below and apex above. Cup-shaped processes of the cell encompass various germ cell types. A study of specific cellular relationships. *American Journal of Anatomy*. 167, 181–192.

differentiated spermatogonia. After their last division, the spermatogonia enter meiosis as preleptotene spermatocytes. These cells migrate upwards away from the base of the seminiferous tubule and cross the Sertoli–Sertoli junction.

Much of what is understood about SSC function and regulation derives from studies of the mouse. It should be noted, however, that the mouse and human differ in significant ways (Singh et al., 2017). In contrast to the mouse, there are two populations of SSCs in humans and other primates: mitotically active stem cells, referred to as A_{pale} spermatogonia, that sustain spermatogenesis in the normal testis; and reserve stem cells, referred to as A_{dark} spermatogonia, that replicate after loss of substantial numbers of

Fig. 4 Diagram of spermatogonial stem cell self-renewal, and stem cell differentiation to form type A1 spermatogonia.

spermatogenic cells. The stem/progenitor cells also differ from their mouse counterparts because they divide only once or twice before differentiating. Despite the limited numbers of replications, the number of sperm produced per gram of human testis is similar in human and mouse, suggesting that the numbers of stem/progenitor cells in the human testis must be far greater than in the mouse. GDNF is considered to play an important *in vivo* role in the regulation of both human and mouse. As in the mouse, human Sertoli cells express GDNF mRNA, and transcripts encoding the subunits of the GDNF receptor GFRA1 and RET are detectable in spermatogonia isolated from both mouse and human testes. Furthermore, GFRA1, the ligand-binding domain of the GDNF receptor, is expressed by human A_{pale} and A_{dark} spermatogonia.

Meiosis

Meiosis results in the production of haploid spermatids (Criswold, 2016). In meiosis, DNA replication occurs during the S-phase of interphase. Immediately following DNA replication, the cells enter meiotic prophase (Meiosis I). During leptotene of meiotic prophase, the chromosomes, each consisting of two sister chromatids, become apparent in the nuclei. During zygotene, homologous chromosomes begin to pair, facilitated by the formation of the synaptonemal complex. At pachytene, homologous chromosomes pair fully and undergo chromosomal breakage and reunion and thus genetic recombination. During diplotene, the synaptonemal complex begins to degrade and homologous chromosomes separate from one another, remaining bound at chiasmata, the regions where crossing-over occurred. In the mammalian female, oocytes develop to this stage before birth and remain in this state until meiosis is resumed in preparation for ovulation. In the male, there is no arrest during meiosis. Rather, the process is continuous. At diakinesis, chromosomes condense and the meiotic spindle begins to form. At metaphase I, homologous chromosomes align on the metaphase plate. At anaphase I, homologous chromosomes, each consisting of a pair of sister chromatids, move to opposite poles. The first meiotic division effectively ends when the chromosomes arrive at the poles at telophase. The daughter cells have the haploid chromosome number, and each chromosome is comprised of a pair of chromatids. Meiosis II is not preceded by DNA synthesis. Chromatids separate into the resulting daughter cells such that the haploid spermatids receive half the DNA amount.

Spermiogenesis

Spermatids, the products of meiosis, mature to become elongated spermatids (aka spermatozoa) during spermiogenesis (O'Donnell, 2015). In part, spermatid maturation involves the elongation of the nucleus and the condensation of chromatin, the latter a consequence of the replacement of histones by arginine- and cysteine-rich protamine during spermatid elongation. Condensation of the nucleus results in transcriptionally inactive, tightly packed chromatin. Spermatid maturation also involves the formation of the acrosomal granule by the Golgi apparatus, and its subsequent elaboration over the head of the nucleus. The acrosome contains hydrolytic enzymes that are required for sperm penetration through egg investments during fertilization. Additionally, the sperm tail forms, and the mitochondria gather at the base of the nucleus, forming the midpiece. Testicular spermatozoa, which lack motility or the ability to penetrate an egg, gain both qualities in the epididymis.

Cycle of the Seminiferous Epithelium

Spermatogenesis is a continuous process which, as described above, involves spermatogonial proliferation and differentiation, meiosis and spermiogenesis (Russell et al., 1983). Spermatozoa are produced at all times, from puberty through old age. In

Fig. 5 Stages of the cycle of the seminiferous epithelium in the rat. The vertical columns, designated by Roman numerals, show progressive associations (stages) of spermatogenesis, including spermatogonia, spermatocytes and spermatids. These associations occur over time at any given location of the tubule. Modified from Fig. 4-1, Russell, L.D., Ettlin, R.A., Sinha Hikim, A.P., and Clegg, E.D. (1983) In: *Histological and Histopathological Evaluation of the Testis*. Cache River Press, Clearwater, FL.

any given location along a seminiferous tubule, cohorts of spermatogonia, spermatocytes and spermatids are seen, developing concurrently (Figs. 2 and 5). Spermatogonia are situated along the basement membrane, spermatocytes are closer to the tubule lumen, and spermatids are nearest the lumen. The cells are not arranged at random, but rather, at any location along the tubule, cells are organized into well-defined stages defined by the four to five germ cell cohorts that are present. Any given cross section of seminiferous tubule will contain one or two generations of spermatogonia, one or two generations of spermatocytes, and one or two generations of spermatids. The various generations of germ cells form identifiable morphological stages, defined by specific sets of cell associations that follow each other over time in any given area of seminiferous tubule. Different regions of a given seminiferous tubule will contain different stages of the cycle, the net result of which is the continuous and asynchronous production of sperm. The cellular associations present at any given location change over time as the cells differentiate. The series of cellular associations that ultimately produce spermatozoa from spermatogonia is referred to as the cycle of the seminiferous tubule (Fig. 5). The term “cycle” is used because any specific cellular association that is present at a given time and location will be seen again at a later time at that same tubular location. The cycle continues from puberty throughout the life of the male. The time that is required for spermatozoa to be produced from spermatogonia varies according to the species. In the human, spermatogenesis occurs over the course of about 64 days; and in the rat about 48 days.

Cells do not move laterally along the length of the tubules. However, observation along the length of a tubule reveals that the stages are largely in consecutive order, though there are short reversals of this segmental order, called modulations. The sequential order of stages along the tubules constitutes what is referred to as “the wave of the seminiferous epithelium.”

Hormonal and Paracrine Regulation of Spermatogenesis

A number of factors, both endocrine and paracrine, are known to regulate germ cell survival during spermatogenesis. Testosterone, produced by Leydig cells of the testicular interstitial compartment, is essential for spermatogenesis (Zirkin, 1998). Prolonged reduction in intratesticular testosterone concentrations can result in significant germ cell loss and thus reduced testicular volume (Fig. 6) and ultimately infertility (Wang et al., 2016). Little is known about the cellular and molecular mechanisms that underlie the regulation of spermatogenesis by testosterone. The situation is complicated by the fact that germ cells, whose survival depends on adequate concentrations of testosterone, do not express the androgen receptor. Thus, the germ cell apoptosis that results from decreased intratesticular testosterone concentration is considered to be mediated by the androgen receptor-expressing somatic Sertoli cells. In addition to testosterone, the maintenance of spermatogenesis also may be dependent on follicle-stimulating hormone (FSH). The Sertoli cells contain receptors for both testosterone and FSH. Paracrine factors from Sertoli cells, some of which may be regulated by testosterone, play an integral role in regulating spermatogenesis.

Fig. 6 Effects of prolonged reduction in intratesticular testosterone concentrations on testicular volume. The reduced testicular volume results from germ cell loss.

Summary

The production of male gametes is essential to the survival and perpetuation of species. Cellular and molecular changes during spermatogenesis are exquisitely regulated by both extrinsic and intrinsic factors. As perturbations at any stage of spermatogenesis can result in non-functional gametes or abnormal embryos, the importance of spermatogenesis is apparent.

Prospermatogonia

Massimo De Felici, University of Rome Tor Vergata, Rome, Italy

© 2018 Elsevier Inc. All rights reserved.

Introduction

In mammals, prospermatogonia, also called gonocytes or prespermatogonia, are transient cells of the male germ cell line between the primordial germ cells (PGCs) and the spermatogonia stem cells (SSCs). PGCs are embryonic cells coming from the extraembryonic mesoderm of the yolk sac wall which colonize the gonadal anlagen to give rise to oogonia in the female and prospermatogonia in the male. SSCs are the stem cells of the postnatal testis derived from prospermatogonia which sustain spermatogenesis during the adult life.

The lifetime of prospermatogonia spans from the embryonic to the early postnatal or pre-pubertal period depending on the species. For example, in rodents, where the most part of studies about these cells have been performed, this period lasts about 2 weeks, whereas in primates it takes several months or some years. The transient nature of prospermatogonia is testified by their morphological and molecular heterogeneity due to the variety and dynamics of the processes occurring in such cells. These characteristics are exacerbated in human by the asynchrony of these processes resulting in the presence of prospermatogonia at different developmental stages at the same time in the same testis cord region. Such heterogeneity led to the proposal of various prospermatogonia subpopulations identified with different terminology.

Only scant information is available about human prospermatogonia, due to the obvious difficulty to obtain these cells. Such information should be, however, of great biological and clinical interest since several developmental processes occur in prospermatogonia crucial for male fertility and probably, if defective, at the origin of certain types of testicular germ cell tumors (TGCTs). In fact, disturbance of testis development in fetal life can result in testicular dysgenesis syndrome (TDS), which includes disorders, such as cryptorchidism, hypospadias, infertility, and TGCTs.

Formation

Prospermatogonia derive from PGCs during the embryonal–fetal period. In the human embryo, between the 2nd and 3rd week, the progenitors of PGCs probably arise in the posterior region of the epiblast, one of the two cell disk (the other being the hypoblast) forming the embryo proper at this time (De Felici, 2016) or in the forming extraembryonic amnios membrane (Sasaki et al., 2016). Shortly before the beginning of gastrulation, the progenitors move in the extraembryonic mesoderm/endoderm of the yolk sac where they possibly become PGCs and from which, around 4th week, PGCs start migration toward the gonadal anlagen (or gonadal ridges) developing in the celomatic wall of the embryo hindgut.

In the developmental testis (5th–6th week), PGCs become progressively enclosed within the testis cords by pre-Sertoli cells; this starts about on 7th week and continue up to the end of first trimester of pregnancy. During this period, PGCs differentiate into prospermatogonia at the center of the cords (for a review, see De Felici, 2016) (Fig. 1).

Heterogeneity

On the basis of morphological and molecular studies human prospermatogonia have been differently classified and named (for reviews, see Culty, 2013; McCarrey, 2013).

According to early studies, Wartenberg et al. (1971) on morphological grounds distinguished three types of human prospermatogonia: primitive phase 1-gonocytes, phase 2-gonocytes, and the more differentiated, fetal spermatogonia. Gondos and Hobel (1971), however, distinguished only two types of fetal germ cells according to their localization within the tubules: isolated and centrally situated gonocytes, and fetal spermatogonia clustering near the basal lamina. Fukuda et al. (1975), again described three types of germ cells within human testis from 9 to 30 weeks *postconception*: the gonocytes, the intermediate cells and the fetal spermatogonia. The gonocytes were described as cells with the highest nucleus–cytoplasmic ratio, a round nucleus with a centrally located, prominent nucleolus, a cytoplasm displaying a well-developed Golgi apparatus, lipid droplets and parallel arrays of short cisternae of the rough endoplasmic reticulum. The intermediate cells were found to extend several cytoplasmic processes and to contain a moderate number of long, branched and/or widened reticulum cisternae. Intermediate cells were often connected to one another by intercellular cytoplasmic bridges. Fetal spermatogonia also displayed cytoplasmic bridges. These latter showed the lowest nucleus–cytoplasmic ratio and a more condensed chromatin. The mitochondria were situated close to the nucleus. Glycogen particles, polyribosomes, and chromatoid bodies (“nuage”) were present in all the three germ cell types. All these morphologically distinct fetal germ cells can be considered prospermatogonia in progressive stages of differentiation.

At molecular level, early prospermatogonia (equivalent to gonocytes) have been then reported to express several genes and surface markers in common to PGCs and typical of pluripotent cells such OCT4, NANOG, c-KIT, AP-2γ, placental alkaline phosphatase (PLAP), and SSEA-1, SSEA-4, M2A. Most of these markers are downregulated during the subsequent migratory phase and differentiation and progressively replaced by others, more germ cell specific, such as VASA (or DDX4), PUM2, DAZL, and MAGE-A4

Fig. 1 Mouse prospermatogonia in the center of a testis cords. (A) Paraffin section stained with E&E, (B) immunolocalization in paraffin section of VASA in the cytoplasm of prospermatogonia (*red*) (cell nuclei are stained with the fluorescent *blue* dye DAPI), and (C) semithin toluidine *blue* stained section for transmission electron microscope.

(Gaskell et al., 2004 and references here in). Interestingly, most of the pluripotency and some of the more advanced prospermatogonia developmental stage markers, are expressed at various level in the most part of TGCTs, supporting the hypothesis that this tumors originate from undifferentiated or poor differentiated prospermatogonia (for a review, see Dolci et al., 2015).

Proliferation

Colonizing PGCs and prospermatogonia in the center of the testis cords, undergo active proliferation. The number of germ cells per testis shows an exponential increase between 6 and 9 weeks *postconception* from about 10,647 to 74,626. In third-trimester samples, this number has been estimated to increase to $1.5\text{--}3.8 \times 10^6$, which is consistent with further mitotic activity of prospermatogonia in the second trimester (Cortes, 1990; Mamsen et al., 2011). The rate of increase in germ cell numbers is then reduced and low proliferation is detected in prospermatogonia in the late gestational period, followed by a small increase, between 2.5- and 6-month-old infants. So that, differently than in rodents, human prospermatogonia do not appear to undergo a period of complete proliferative quiescence.

In rodents, several molecules, mostly produced by testis somatic cells, have been reported to induce or inhibit prospermatogonia proliferation in *in vitro* models. For example, retinoic acid (RA) was found to increase the proliferation of fetal rat prospermatogonia. In mouse and/or in rat, PDGF-BB, 17- β -estradiol, and RA were shown to induce neonatal prospermatogonia proliferation whereas activin A, prostaglandin D2, FGF9, androgen, and T3 hormones, were reported to be negative regulators of fetal prospermatogonia proliferation. Moreover, Activin A/Nodal/TGF β signaling appears to inhibit the proliferation both of fetal and postnatal prospermatogonia in the mouse. While stimulation of proliferation seems to occur through classical MAPK and/or PI3K-dependent pathways, SMAD2/3 and p38 act in concert to inhibit mouse prospermatogonia proliferation (for a review, see Manku and Culty, 2015). The final targets of the inhibitors of proliferation is likely to be the activation of genes such as *Nanos2* and *Dnd1*, encoding RNA binding proteins, upregulation of the CDK inhibitors p15, p16, p21, and p27 and of the tumor suppressor RB1 protein and downregulation of some cyclins as for example E1, E2, and D3. Finally, the expression of transcription factors such DMRT1, baso-nuclin2, and FOX1, were reported to be associated to the G0 quiescence of mouse prospermatogonia (for a review, see De Felici and Farini, 2012).

If these factors are involved in the control of human prospermatogonia proliferation is not known. Moreover, since the marked asynchrony of such processes in human, we must assume that the supply of stimulatory or inhibitory proliferation factors to prospermatogonia must be finely regionally regulated.

Migration

The various stages of the prospermatogonia migration from the center to the testicular cord periphery are indicated by changes in morphological features and, in particular, by the extension of cytoplasmic processes toward the basal lamina (Fukuda et al., 1975) (Fig. 2). Reaching such matrix, some prospermatogonia appear to be arranged in pairs and groups connecting by intercellular bridges derived by incomplete cytokinesis (Wartenberg et al., 1971; Gondos and Hobel, 1971).

In contrast to rodents, where prospermatogonia migration starts and ends during the first week after birth, human prospermatogonia commence to migrate around the end of the second trimester of gestation and continue up to 8 months after birth. Despite that this migration coincides with the physiological activation of the hypothalamic-pituitary-gonadal axis, characterized by a surge in serum gonadotropins and testosterone levels at age 1–3 months, data from mice with global inactivation of the androgen receptor, FSH receptor or lacking GNRH, indicate that androgens and gonadotropins are not required for prospermatogonia migration and differentiation.

A current list of factors that have been directly shown to influence prospermatogonia migration in rodents includes c-KIT/stem cell factor, various adhesion molecules, thyroid hormone, PDGF receptor beta, and Notch. In such species, a model has been proposed in which the ADAM–integrin–tetraspanin complex, known to constitute a network of membrane microdomains called the “tetraspanin web,” is involved in the migration of prospermatogonia (for a review, see Culty, 2009).

Programmed Cell Death

Programmed cell death (PCD) affects primarily prospermatogonia at the center of the developing sex tubules. The physiological significance of this process is still not clear. Some researchers have hypothesized that it may cooperate in maintaining an optimal germ cell/Sertoli cell ratio. Others suggest this as a selection mechanism to eliminate chromosomally abnormal cells, eventually appearing because of high proliferation rate.

In the mouse, prospermatogonia death occurs primarily in the middle of the fetal period and again around birth. According to morphological observations and molecular markers, such process occurs with typical apoptotic features. Studies on knockout mice have identified some important players of the process. For example, haploinsufficiency of the zinc-finger transcription factor *Zfp148* has been shown to cause complete loss of prospermatogonia correlated with impaired phosphorylation of p53. Another member of the p53 family, p63, localized in the nucleus of the prospermatogonia, might be also involved in triggering their PCD. The RNA binding protein *Dazl* is, on the contrary, important for prospermatogonia survival since disruption of the gene leads to their massive degeneration. Bcl-2 family members are also positively or negatively involved in prospermatogonia survival. In fact, in Bcl-x hypomorphic mice, severe loss of prospermatogonia occurs and the phenotype is rescued by concomitant disruption of Bax. Interestingly, some authors reported that testis somatic cells play an active role in prospermatogonia PCD. Extrinsic apoptotic pathways are usually initiated by binding to cell surface “death receptors,” including Fas (CD95) and TNF receptor1, by their specific ligands. Interestingly, c-FlipL, a natural inhibitor of Fas-mediated apoptosis, is expressed at high level in mouse prospermatogonia and might have a role in protecting prospermatogonia from Fas-dependent apoptosis (Giampietri et al., 2006).

The second postnatal round of death in mice does not occur with typical apoptosis features so that other mechanisms can be involved.

Fig. 2 Diagram of prospermatogonia formation and differentiation within a testis cord. (A) Prospermatogonia (green nucleus and white cytoplasm) arise from primordial germ cells (pale gray nucleus and dark gray cytoplasm); (B) and (C) prospermatogonia migration from the center to the testicular cord periphery is indicated by changes in morphological features (in particular, by the extension of cytoplasmic processes toward the basal lamina), in expression of adhesion proteins and receptors (red plasmalemma), several transcription factors and epigenesis (green nucleus). Moreover, programmed cell death occurs in significant number of prospermatogonia (black nucleus). Cells originated from prospermatogonia laid onto the basal lamina are stem cell spermatogonia.

In human, significant level of apoptosis occurs in fetal testis during the first trimester, both in Sertoli and Leydig cells and prospermatogonia and continues throughout pregnancy. RA could be one of the factors involved since its presence at 10^{-6} M for 4 days in culture increases significantly apoptosis in testis obtained from 6 to 10 weeks.

Epigenesis

Shortly after specification, throughout migration and for a couple of days after gonad colonization mouse PGCs undergo extensive epigenetic reprogramming (changes in gene expression due to mechanisms, mainly DNA methylation/demethylation and histone modification, other than changes in DNA sequence). Such process is a key feature of PGC development and includes wide genome demethylation and erasure of the DNA methylation marks associated with imprinted genes, allowing genome reprogramming of the nascent germ cells and the establishment of sex-specific imprints during gametogenesis. There are also extensive changes in several histone marks. For a review, about of epigenesis in mouse PGC, see [De Felici \(2011\)](#).

In human PGCs, a few observations have been reported with regard to chromatin changes and DNA demethylation. Nevertheless, a timeline and some characteristics of these events are becoming to be available also thanks to the in vitro models of PGC-like formation for stem cell lines in vitro ([Tang et al., 2015](#)). In this regard, immunohistochemical studies and DNA methylome analyses have shown that both female and male fetal germ cells are hypomethylated already at 5th and 6th weeks of gestation when most of them are still migrating or have just arrived in the developing gonads. Like in mouse, consistent with global demethylation, UHRF1 (a protein involved in the maintenance of DNA methylation), was not detectable in proliferating oogonia/prospermatogonia while de novo DNA methyltransferase DNMT3A and DNMT3B were repressed. Also resembling mouse PGCs, despite global hypomethylation, potentially hazardous retrotransposons such as the LINE SINE-VNTR-*Alu* (SVA) and endogenous retrovirus (ERV) elements remain methylated in gonadal human PGCs. Interestingly, other mechanisms, including histone modifications or PIWI-interacting RNAs (piRNAs), have been identified in germ cells to inactivate transposable elements during global demethylation. Remarkably, some loci associated with metabolic and neurological disorders were also resistant to DNA demethylation, revealing potential for transgenerational epigenetic inheritance that may have phenotypic consequences.

The subsequent re-establishment of methylation and correct imprinting are essential for ensuring functional germ cells. In contrast to mouse prospermatogonia, which remain demethylated for only a few days, human prospermatogonia remain hypomethylated for weeks and only show signs of re-methylation in the II trimesters (around 16th week onward). As for chromatin modifications, at around 16th–20th weeks human prospermatogonia were reported to have absence/low levels of repressive H3K9me2, H3K27me3, and H3K9me3 modifications but high levels of permissive H3K9ac and H2A.Z marks. In the mouse, global DNA methylation levels rise from ~10% in 13.5 dpc PGCs to ~50% in 16.5 dpc prospermatogonia, coinciding with redistributing the active marks of H3K4me2/3 and H3K36me3 in prospermatogonia. The elevated expression of DNA methyltransferase 3A/3B/3L (DNMT3s) during these stages suggests the potential contribution of de novo DNA methylation at this stage. The time course of complete re-methylation and paternal imprinting establishment in humans are not known. However, some results allow dating the completion of DNA methylation pattern to occur sometime postnatally, before puberty, while imprinting continues during spermatogonial differentiation and early stages of meiotic prophase I.

These results support the notion that human PGCs undergo a pattern of genome reprogramming similar on the whole to the mouse model but with differences in timing and chromatin changes. The significance and importance of such differences remain, however, to be clarified.

Differentiation

After reaching the periphery of the developing tubules, prospermatogonia differentiate into SSCs which in turn will give rise to differentiating spermatogonia ([Fig. 2](#)). In humans, these processes are gradual and asynchronous, which means that germ cells at different stages of development will be present throughout fetal and neonatal development.

The differentiation step from prospermatogonia to SSCs is particularly important since, as reported above, carcinoma in situ (CIS) cells, the progenitors of the most part of TGCTs, are believed to arise from arrested/dysfunctional prospermatogonia. In this context, it has been reported that in the normal human testis during the perinatal period, those prospermatogonia which remain OCT4 positive are almost exclusively located in the center of the seminiferous cords while increasing intensity of VASA immunostaining coincides with relocation of prospermatogonia to the basal membrane in the second trimester of pregnancy. In older children with disorders of sexual development, who are at increased risk of TGCTs, prospermatogonia expressing OCT4 are reported to be both more numerous and located at the basal lamina.

In the mouse, known genes expressed in SSCs that must presumably be activated during their differentiation from prospermatogonia, include *Gfra1* and *Ret*, encoding the receptor of the growth factor GDNF, and *Plzf* and *Nanos2*, encoding transcription factors likely important for the maintenance of the SSC stemness. Moreover, the integrins $\beta 1$ and $\alpha 6$ and the transcription factor FOXO1 have been described to undergo nuclear-cytoplasm translocation when prospermatogonia differentiate in SSCs. In this latter, FOXO1 will be subsequently relocated into the nucleus. According to some authors, FGF signaling is a master regulator of prospermatogonia to SSC transition and acts upstream of GDNF and RA signaling for the activation of the MEK/ERK and PI3K/Akt pathways.

Several studies in mice suggest that two different populations of prospermatogonia are present in the neonatal testis, in which one subpopulation progress directly into differentiating spermatogonia and complete the first round of postnatal spermatogenesis, whereas a second population transforms into SSCs that than provide the basis for subsequent rounds of spermatogenesis. Whether this two waves of spermatogenesis are conserved in human is currently unknown. According to a widely accepted model for human spermatogenesis in the adult, SSCs correspond to single type-A_{dark} spermatogonia, which can self-renew, while paired type-A_{pale} spermatogonia are differentiating daughter cells connected by an intercellular bridge.

Introductory Overview

Spermatogenesis is a highly organized process that produces millions of sperm each day in postpubertal mammals (Sharpe, 1994; Gupta et al., 2000; Thayer et al., 2001). This productivity depends on the activity of spermatogonial stem cells (SSCs), which are the adult tissue stem cells in the testes that balance self-renewing divisions with differentiating divisions to maintain the stem cell pool and fuel spermatogenesis, respectively (Clermont and Bustos-Obregon, 1968; Huckins and Oakberg, 1978; Tegelenbosch and de Rooij, 1993; de Rooij and Grootegeod, 1998). When SSCs differentiate, they give rise to progenitor spermatogonia that undergo a species-specific number of transit amplifying mitotic divisions, followed by two meiotic divisions and spermiogenesis (morphological transformation) to produce terminally differentiated sperm (Fig. 1). Spermatogenesis occurs in a cyclic manner along the length of the seminiferous tubules, ensuring continuous sperm production throughout the postpubertal life of mammals. In mice, the cycle of the seminiferous epithelium is divided into 12 distinct stages (I–XII) and each stage is defined by specific associations of spermatogonia, spermatocytes, spermatids and sperm. A segment of seminiferous tubules progresses through all 12 stages every 8.5 days (Russell et al., 1990). SSCs reside in a specialized niche located on the basement membrane of the seminiferous tubules where they are in direct contact with the basement membrane and Sertoli cells, which produce some of the paracrine factors required to regulate self-renewal and differentiation fate decisions. Stem, progenitor and differentiating spermatogonia are all located on the basement membrane of the seminiferous tubules. Differentiating spermatogonia give rise to spermatocytes that initiate meiosis, migrate off the basement membrane and give rise to secondary spermatocytes, spermatids and sperm. The identity of the SSC pool is the subject of active research and debate.

Spermatogonial Development—Clonal Dynamics

Spermatogenesis arises from a population of A_{single} (A_s) spermatogonia located on the basement membrane of seminiferous tubules (Fig. 2A, red) (Huckins, 1971a; Oakberg, 1971; de Rooij, 1973). A_s spermatogonia are rare, comprising 0.03% of all germ cells in the mouse testis; they are evenly distributed along the basement membrane of the seminiferous tubules; have a relatively large nuclear

Fig. 1 *Mammalian Spermatogenesis.* The pool of diploid spermatogonial stem cells (SSCs) balance self-renewing and differentiating divisions to maintain the stem cell pool as well as continuous sperm production. Once committed to differentiate, SSCs give rise successively to undifferentiated progenitor spermatogonia and differentiating spermatogonia through a species-specific number of transit amplifying mitotic divisions that can dramatically increase the yield of sperm from a single stem cell. Differentiating spermatogonia give rise to primary spermatocytes, which undergo two meiotic divisions to produce haploid spermatids that undergo spermiogenesis to produce terminally differentiated sperm.

*These authors contributed equally to this work.

Fig. 2 Testis anatomy *in toto*, whole mount and cross-sectional views. (A) The mammalian testis is comprised of numerous seminiferous tubules where spermatogenesis occurs. Undifferentiated A_{single} (red), A_{paired} (yellow) and A_{aligned} (green) spermatogonia are located on the basement membrane of seminiferous tubules. Undifferentiated spermatogonia expand clonally through transit-amplifying mitotic divisions, where individual cells remain connected via intracytoplasmic bridges, and give rise to differentiating spermatogonia (purple). Differentiating spermatogonia, which are also located on the basement membrane of seminiferous tubules, undergo a species-specific number of transit amplifying divisions (see Fig. 3) before giving rise to primary spermatocytes that migrate off the basement membrane and initiate meiosis. (B) Macroscopic view of whole mouse testis. (C) Whole mount preparation of mouse seminiferous tubules stained with PLZF (ZBTB16), a marker of undifferentiated A_{single} , A_{paired} and A_{aligned} spermatogonia. (D) Cross section of seminiferous tubule stained with PLZF. Note that it is not possible to determine clonal arrangement (A_{single} , A_{paired} , A_{aligned}) in cross sectional views of the seminiferous tubules. Spermatogonial terminology is for rodent but conceptually relevant to spermatogonial development for monkeys and humans (see text).

to cytoplasmic ratio and diffuse chromatin (lacking heterochromatin) (Tegelenbosch and de Rooij, 1993). When A_{s} spermatogonia divide they produce A_{paired} (A_{pr}) spermatogonia (Fig. 2A, yellow) that either complete cytokinesis to produce two new A_{s} spermatogonia (self-renewal) or stay connected via an intracytoplasmic bridge and produce a chain of four A_{aligned} (A_{al4}) spermatogonia at the next division. Subsequent divisions of A_{al4} spermatogonia give rise to A_{al8} and A_{al16} spermatogonia (Fig. 2A, green). A_{s} , A_{pr} and A_{al} are collectively termed, undifferentiated spermatogonia. A_{s} and A_{pr} are equally distributed along the length of the seminiferous tubules, while A_{al} are distributed in a stage-dependent manner with peak numbers in the mid-stages before the appearance of differentiating type A1 spermatogonia (Tegelenbosch and de Rooij, 1993). The transition to differentiating type A1 spermatogonia can occur from clones of A_{s} , A_{pr} or A_{al4} , but most frequently occurs from clones of A_{al8} or A_{al16} (Nakagawa et al., 2010; Griswold and Oatley, 2013; de Rooij and Russell, 2000; de Rooij and Griswold, 2012). Eight successive transit amplifying divisions from A1 spermatogonia in rodents give rise to differentiating spermatogonial types A2, A3, A4, Intermediate and B, followed by primary spermatocytes, secondary spermatocytes and round spermatids. With a total of 10 transit amplifying mitotic divisions followed by two meiotic divisions, a single stem cell that commits to differentiate can theoretically produce 4096 sperm in rodents (Russell et al., 1990) (Fig. 3, Top row).

The Spermatogonial Stem Cell in Rodents

A_{s} , A_{pr} and A_{al} spermatogonia all have an undifferentiated appearance with homogenous, diffuse chromatin. They can be distinguished by clone size in whole mount preparations of seminiferous tubules (Fig. 2A center and C), but not in histological cross section (Fig. 2A right and D). This distinction is important because there is general consensus that A_{s} spermatogonia comprise at least a part of the spermatogonial stem cell pool and that stem cell activity decreases with increasing clone size. In 2011, Oatley and colleagues identified for the first time, a molecular marker (ID4) with expression that was limited to A_{s} spermatogonia on the basement membrane of seminiferous tubules (Oatley et al., 2011). ID4 represents a subpopulation of A_{s} spermatogonia; it is co-expressed with GFRa1 and PLZF, but represents a subpopulation of GFRa1⁺ and PLZF⁺ cells. ID4⁺ cells can be maintained and

Fig. 3 Spermatogenic lineage development in rodents, monkeys and humans. In the rodent, monkey and human, spermatogonial development begins with a single spermatogonia ($A_{\text{single}}-A_s$ in rodent, $A_{\text{dark}}/A_{\text{pale}}$ in monkey and human)-red nucleated cell, which can divide to either self-renew or remain attached to form a clone of two cells ($A_{\text{paired}}-A_{\text{pr}}$)-orange nucleated cell. Depending on the species, the clone of two cells undergo one or more mitotic divisions as undifferentiated spermatogonia-green nucleated cells. Each mitotic division is represented by a black arrow. In the rodent, A_{aligned} (A_{al}) clones 4, 8 or 16 cells could result from these mitotic divisions before differentiation to type A1 spermatogonia without mitotic division. In monkeys and humans, $A_{\text{dark}}/A_{\text{pale}}$ clones of two or four divide and differentiate to become type B spermatogonia with clone sizes of four or eight. The number of mitotic divisions in differentiating spermatogonia (blue periphery cells) also vary by species. There are six generations of differentiating spermatogonia in the rodent. This includes the A1 (clone size-16), A2 (clone size-32), A3 (clone size-64), A4 (clone size-128), intermediate spermatogonia (Int, clone size-256) and type B spermatogonia (clone size-512). Differentiating type B1 spermatogonia in monkeys and type B spermatogonia in humans correspond to type A1 differentiating spermatogonia in rodents based on nuclear morphology and cKIT expression. There are four generations of differentiating type B spermatogonia in monkeys (B1–B4), but only one generation of differentiating B spermatogonia in humans, which has a significant impact on sperm output (right column). In all three species, the last generation of differentiated spermatogonia (blue cell in the box) undergo a division to enter meiosis (first pink arrow) and the resulting primary spermatocytes (two pink cells) undergo first meiotic division (second pink arrow), which results in the production of secondary spermatocytes (four pink cells). The second meiotic division (third pink arrow) results in postmeiotic round spermatids (eight purple cells). Sperm output per gram of testicular tissue per day from rodents, monkeys and humans is indicated in the last column.

expanded in culture and regenerate spermatogenesis when transplanted into infertile recipients. Relative to $ID4^{\text{bright}}$ cells, transplantable stem cell activity is substantially reduced in $ID4^{\text{dim}}$ and $ID4^-$ cells, but not absent (Oatley et al., 2011; Chan et al., 2014; Helsel et al., 2017). Since 2011, PAX7 (Aloisio et al., 2014), BMI1 (Komai et al., 2014) and EOMES (Braun et al., 2017) have also emerged as markers restricted to A_s spermatogonia on the basement membrane of seminiferous tubules. Each marker is expressed by a sub-population of $GFRa1^{+}$ cells and a subpopulation of A_s spermatogonia. Cells expressing each of these markers produce and maintain colonies of spermatogenesis after transplantation and/or in lineage tracing studies (see Table 1 for list of spermatogonial markers).

It seems reasonable to suppose that the stem cell pool also extends to some A_{pr} spermatogonia because A_s must transit through an A_{pr} state in the process of self-renewal (this concept is nicely reviewed in de Rooij and Griswold, 2012). In fact, self-renewal and differentiation could be precisely balanced if half of A_{pr} spermatogonia completed cytokinesis to produce two new A_s , while the other half produced chains of $A_{\text{al}4}$ at the next division. However, pulse labeling of $GFRa1^{+}$ cells indicated that the balance was skewed more toward the A_{pr} to $A_{\text{al}4}$ transition than the A_{pr} to 2 A_s transition. To reconcile this apparent imbalance, Hara and colleagues provided live video imaging $GFRa1$ -GFP spermatogonia data to suggest that clone fragmentation (e.g., $A_{\text{al}4}$ fragment to $A_{\text{al}3} + A_s$ or $A_{\text{pr}} + 2A_s$ or 4 A_s) was an important contributor to maintenance of the A_s pool (Hara et al., 2014) (Fig. 4). While the fate of the fragmenting clones could not be documented in that study, clones of $A_{\text{al}3}$ have been observed by others and apoptosis rarely occurs in undifferentiated spermatogonia (Suzuki et al., 2009; Gassei and Orwig, 2013). However, one concern with the clone fragmentation model is that it does not account for the contribution of $GFRa1$ negative cells to the pool of A_s (Suzuki et al., 2009; Gassei and Orwig, 2013) or the pool of transplantable stem cells (Grisanti et al., 2009; Garbuzov et al., n.d.).

Spermatogonial Tool Box for Rodents

Spermatogonial stem cells are rare in rodent testes because they are outnumbered by the progenitor and differentiating spermatogonia, spermatocytes and spermatids that they produce; and this challenges efforts to understand the molecular regulation of SSC function. Therefore, to learn the molecular features of SSCs, it was necessary to (1) study testes early in development prior to spermatogonial differentiation (Shima et al., 2004); (2) study testes in which differentiating germ cells were depleted (Orwig et al., 2008); (3) enrich transplantable SSCs by FACS or MACS (Hermann et al., 2015) or (4) modulating growth factors in SSC culture (Oatley et al., 2006). Each of these approaches identified molecules expressed by stem and progenitor spermatogonia and provided

^aWe attempted to sort the germ cell markers in the order of their expression from undifferentiated to differentiating spermatogonia.

^bExamined with flow cytometry or FACS experiments. FGFR3 and TRA-1-81 are also cell surface markers but not included here because they have not been studied in the context of flow cytometry or FACS.

Fig. 4 *Clone fragmentation model.* In the rodent, molecular markers such as GFR α 1, NGN3 and KIT reveal the clone size of spermatogonia during development. GFR α 1 marks the A_{single} (A_s), A_{paired} (A_{pr}) and A_{aligned} (A_{al}) spermatogonia. However, the intensity of GFR α 1 expression diminishes progressively from A_{pr} to larger clones. In contrast, the intensity of NGN3 expression increases from smaller clones of A_{pr} and A_{al4} to larger clone of A_{al16}. The canonical progression for spermatogonial development is for A_s (red cell) to either self-renew through a complete mitotic division or to form A_{pr} (orange cell) through incomplete cytokinesis following mitotic division. A_{pr} then undergo one or more mitotic divisions to give rise to A_{al} clone of 4, 8 and 16 following one, two or three sequential mitotic divisions. A_{al16} then transit to A1 spermatogonia. However, the clone fragmentation model (Hara et al., 2014) opines that A_{al4} spermatogonia can fragment and contribute to replenishment of the pool of A_s spermatogonial stem cells. Larger clones can also fragment, but this occurs with lower frequency than fragmentation of A_{al4}. Figure reproduced with permission from Spradling, A. and Fan, C. M. (2010). Counterfeiting the family jewels. *Cell Stem Cell*, **6**, 405–406.

clues about pathways that regulate SSC self-renewal and differentiation. However, gene expression data generated from these approaches should be interpreted with caution because the cell populations were heterogeneous and approaches 1, 2 and 4 do not represent the steady state condition with homeostatic balance of self-renewal and differentiation. Although SSC culture does not represent steady state spermatogenesis, it has served as a powerful tool to dissect the mechanisms that regulate SSC self-renewal, differentiation and transplantation potential (Oatley et al., 2006; Lee et al., 2007; Yeh et al., 2011; Chapman et al., 2015).

It is tempting to speculate that a pure population of stem cells could be isolated from the adult testis (with steady state spermatogenesis) by sorting cells that express ID4, PAX7, BMI1 or EOMES. However, that approach could provide an incomplete picture because it is not certain that these four molecules mark the same cell population or that they capture the entire population of SSCs. It is possible, and perhaps likely, that the stem cell pool is dynamic and molecularly heterogeneous; reflecting changes that occur (1) at different stages of the cell cycle, (2) during development, (3) through the stages of the seminiferous epithelium or (4) under conditions of stress. A new generation of *single cell sequencing* technologies (Fluidigm, drop-seq and 10X genomics) now allow researchers to study the heterogeneous mammalian testis and SSC pool with a throughput and resolution that was not previously possible (Hermann et al., 2015; Guo et al., 2017). Furthermore, the drop-seq and 10X platforms can process hundreds of thousands of cells in a single run, which means it is possible to study all cell populations in the mammalian testis without the bias of preselection enrichment. These approaches will certainly expand the list of spermatogonial stem cell markers and may identify subpopulations of spermatogonia that were not previously recognized. So, how should researchers validate the expanding list of SSC markers?

The simplest and least stringent approach to validate candidate markers of undifferentiated stem/progenitor spermatogonia is by RT-PCR or immunocytochemical staining of an experimental cell population with known markers of undifferentiated spermatogonia (e.g., ID4, GFR α 1, PLZF). A more stringent approach is to examine the pattern of candidate marker expression in situ by immunohistochemical analyses in histological cross-section. A marker that is restricted to stem and/or progenitor spermatogonia should be expressed by a subpopulation of cells located on the basement membrane of seminiferous tubules (see PLZF for example, Fig. 2D). Co-staining in histological cross-section helps to establish whether the candidate marker is expressed by undifferentiated spermatogonia (e.g., co-stain with PLZF or GFR α 1), differentiating spermatogonia (e.g., co-stain with cKIT) or both, but does not provide any information about clone size. Immunohistochemical analyses in whole mount preparations of seminiferous tubules (see PLZF example in Fig. 2C) provides the same basement membrane localization and co-expression information as histological cross section as well as information about the clonal arrangement of marked cells. Unfortunately, markers that work well in histological cross section do not always work well in whole mount preparations of seminiferous tubules and vice versa. Each marker needs to be tested empirically in each approach with the appropriate negative and positive controls. In rodent, monkey and human testes, the most undifferentiated spermatogonia are arranged in the smallest clones of 1, 2 or 4 cells.

The descriptive methods described above are useful, but cannot demonstrate the biological potential of an experimental cell population to produce and maintain spermatogenesis, which is the hallmark of SSCs. Ralph Brinster and colleagues pioneered the method of SSC transplantation, which demonstrates the potential of an experimental cell population to regenerate spermatogenesis in the testes of infertile recipients (Brinster and Zimmermann, 1994; Brinster and Avarbock, 1994). More than 20 years after the initial reports, SSC transplantation remains the “gold standard” bioassay of spermatogonial stem cells. In recent years lineage tracing has emerged as a powerful tool that demonstrates the in vivo capacity of marker positive cells to produce and sustain spermatogenesis over a long period of time (Nakagawa et al., 2007; Hara et al., 2014; Aloisio et al., 2014; Komai et al., 2014). Lineage tracing results can be a little more difficult to quantify than transplantation, but have the advantage that stem cell potential can be assayed in the steady state condition of the adult testis.

Stem, Progenitor and Differentiating Spermatogonia in Nonhuman Primates and Humans

Nonhuman primate and human testes contain two morphologically distinct types of undifferentiated spermatogonia, classified as A_{dark} and A_{pale} based on differences in nuclear architecture and staining with hematoxylin in histological cross sections (Clermont and Leblond, 1959; Clermont, 1966). Clermont initially proposed that A1 spermatogonia (later renamed A_{dark}) were the SSCs that gave rise to progressively more differentiated A2 (later renamed A_{pale}) and B spermatogonia. However, he later revised this model based on observations that A_{dark} failed to label after a single bolus injection of [^3H]-thymidine. Since A_{dark} did not appear to self-renew under steady state conditions, he proposed that A_{dark} and A_{pale} represented reserve and active stem cells, respectively (Clermont, 1969). In this reserve stem cell model, spermatogenesis is maintained by the “active” A_{pale} SSCs that self-renew to maintain the A_{pale} pool and differentiate to produce spermatogenesis. The “reserve” A_{dark} spermatogonia are quiescent and become active only when A_{pale} are depleted by noxious insult. This notion is supported by observations in nonhuman primates and men indicating that X-irradiation caused a rapid decline in the pool of A_{pale} spermatogonia, which were later replenished by the surviving A_{dark} spermatogonia. Whether A_{dark} are truly quiescent and reserve or slow cycling stem cells that contribute to steady state spermatogenesis is uncertain. Chronic or repetitive administration of a mitotic labeling reagent followed by a period of washout would identify slow cycling stem cells that retain label for an extended period of time, a classic feature of adult tissue stem cells. This is an experiment that has been performed to identify slow cycling, label retaining A_{s} stem cells in rats (Huckins, 1971b) and could be performed in nonhuman primates.

A_{dark} and A_{pale} spermatogonia are present in equal numbers on the basement membrane of the seminiferous tubules and together represent 4% of germ cells in the testis, a frequency that is more than 100-fold greater than rodent A_{s} spermatogonia (0.03%). A_{dark} are evenly distributed along the length of the seminiferous tubules (Similar to rodent A_{s} and A_{pr}), while A_{pale} exhibit a stage-dependent distribution with peak numbers at mid-cycle (similar to rodent A_{al}) that precedes the appearance of differentiating type B1 spermatogonia. A_{dark} and A_{pale} are arranged predominantly as singles, pairs or chains of four (Clermont, 1969), while differentiating B1 spermatogonia appear as clones of 4 or 8, indicating that there are 1–2 transit amplifying divisions in the undifferentiated A_{dark} or A_{pale} spermatogonia before differentiating to B (Ehmcke et al., 2005). In monkeys, four additional transit-amplifying divisions from B1 produce differentiating spermatogonia types B2, B3 and B4, followed by primary spermatocytes. Based on expression of the differentiation marker, cKIT, differentiating type B spermatogonia in nonhuman primates and humans are equivalent to differentiating type A spermatogonia in rodents (Valli et al., 2015). In contrast to rodents, which have a small stem cell pool and many transit amplifying divisions to produce 40×10^6 sperm per gram of testicular parenchyma per day (Fig. 3, top), nonhuman primates achieve a similar sperm output ($41 \times 10^6/\text{g/day}$) with a relatively larger stem cell pool and few transit amplifying divisions (Fig. 3, middle). Sperm output in humans is lower than rodents or monkeys and this can be attributed to the fact that humans have only one generation of differentiating type B spermatogonia (Fig. 3, bottom).

Spermatogonial Tool Box for Nonhuman Primates and Humans

Many markers of undifferentiated and differentiating spermatogonia are conserved from rodents to nonhuman primates to humans (Table 1). While some markers appear species-specific, this could reflect lack of experimentation or antibody availability. Nonetheless, several good markers of undifferentiated, transitioning and differentiating spermatogonia are available and can be used for the methods of RT-PCR, immunocytochemistry (ICC), immunohistochemistry in histological cross-section (IHC-XS) or immunohistochemistry in whole mount preparations of seminiferous tubules (IHC-WM). High throughput single cell sequencing is as accessible for monkey and human studies as it is for mice, assuming the availability of normal tissues (Guo et al., 2017). Monkey to monkey spermatogonial stem cell transplantation is technically feasible and can demonstrate the potential of an experimental cell population to produce and maintain spermatogenesis, long-term (Hermann et al., 2012). However, this approach is not practical or accessible to most researchers as a routine bioassay and impossible for human application. Primate to mouse xenotransplantation has emerged as a valuable surrogate assay of monkey and human SSCs. SSCs from higher primates do not produce complete spermatogenesis in mouse seminiferous tubules. However, they do recapitulate several aspects of spermatogonial function that are not shared with other cell types: (1) they migrate through Sertoli cells to engraft the basement membrane of seminiferous tubules; (2) they proliferate to produce chains and clusters of cells with typical spermatogonial appearance and (3) they persist for long periods of time. One day it may be possible to recapitulate complete spermatogenesis from monkey or human cells in organoid cultures, as previously described for mice (Zhou et al., 2016). However, the mouse results still need to be replicated to establish a robust assay and translation to monkeys and humans will likely require a source of monkey and/or human fetal gonadal cells that are not widely available, if at all.

Concluding Remarks

While different vocabulary is used to describe stem, progenitor and differentiating spermatogonia in rodents, nonhuman primates and humans, many aspects of spermatogenic lineage development are conserved. Undifferentiated spermatogonia, including SSCs, exist as individual cells or small clones of interconnected cells. Transit-amplifying divisions lead to larger clones that are progressively more differentiated. Key differences in spermatogenic lineage development between rodents and higher primates include the

size of the stem cell pool and the number of transit-amplifying divisions that precede meiosis. Many markers of undifferentiated spermatogonia are conserved from mice to monkeys to humans (e.g., GFR α 1, ZBTB16, SALL4). This is true also for transitioning spermatogonia (e.g., SOHLH2, NGN3) and differentiating spermatogonia (e.g., cKIT) (See [Table 1](#) for complete list). It is important to understand how molecular markers of spermatogonia in monkeys and humans correspond with clone size and dark and pale descriptions of nuclear morphology. This knowledge helps to link contemporary studies with the classic literature and identifies parallels between rodents, monkeys and humans. This is particularly important because few modern-day investigators have the experience or patience to conduct classic morphometric studies that were common in the 1950s to 1970s.

Acknowledgements

AF, SD and CD contributed equally to this work with literature review and production of figures and tables. KEO wrote the manuscript. We are grateful to the pioneers cited in this chapter who provided insights using tools of the past that are equally impactful as the tools we use today. We have sprinkled our own experiences throughout this chapter from work that has been supported by the National Institutes of Health (RR18500, AG024992, HD055475, HD008610, HD061289, HD055475, HD075795, HD076412, HD092084), PA Department of Health Tobacco Funds, the US-Israel Binational Science, the Magee-Womens Research Institute and Foundation and the department of Obstetrics, Gynecology and Reproductive Sciences at the University of Pittsburgh School of Medicine.

Spermatocytes

John Schimenti and Priti Singh, Cornell University, Ithaca, NY, United States

Glossary

Primary spermatocyte A developing male germ cell derived from differentiation of a type B spermatogonium. It undergoes the major events of meiosis, including recombination and pairing of homologous chromosomes, before undergoing the first meiotic division.

Secondary spermatocyte A transient cell generated from the division of a primary spermatocyte. Each of these progeny cells undergoes an equational (mitotic-like) cell division to generate two haploid spermatids.

Synapsis Following “pairing,” or close alignment of maternal and paternal homologous chromosomes in primary spermatocytes, synapsis refers to the formation of the SC between these chromosome pairs.

Synaptonemal complex (SC) A structurally conserved, zipper-like tripartite proteinaceous structure along the entire length of homologous chromosomes. The SC is a hallmark feature of maturing primary spermatocytes, and serves to physically tether the homologs together at multiple points along their lengths.

Development of Spermatocytes

Spermatogenesis comprises three main phases: (I) mitoses of spermatogonia, (II) meiosis of spermatocytes ([Fig. 1](#)), and (III) spermiogenesis by which round spermatids change their shapes to become elongated spermatids. Here, we will discuss the transition from phase I to phase II.

Following several rounds of cell division, spermatogonia exit from the mitotic cell cycle and enter meiosis as spermatocytes. This complex process of transition from spermatogonium to spermatocyte has two important elements—*first*, commitment to the spermatogenic differentiation program, and *second*, activation of the meiotic program. Spermatogenic differentiation is influenced by the intricate balance between two sets of antagonistic factors—one promoting and/or maintaining the undifferentiated state of spermatogonial stem cells (SSCs), and the other promoting differentiation of spermatogonia. Retinoic acid (RA) signaling and meiotic competency of germ cells are two important components of differentiation. RA promotes meiotic prophase I entry through the induction of several RA-responsive elements (RARE) ([Koubova et al., 2014](#)). RA production in males begins during embryogenesis, however the induction of RA-responsive genes is delayed by the production by gonadal somatic cells of a cytochrome P450 enzyme (CYP26B1) that efficiently degrades RA. After birth, CYP26B1 is downregulated and RA produced by the testicular Sertoli cells acts upon RAREs of spermatogonia, prompting them to differentiate into primary spermatocytes that enter meiosis ([Saba et al., 2014](#)).

During their development, spermatocytes grow in size ([Bellve et al., 1977](#)). Importantly, during these extensive nuclear reorganization and proliferation processes, cohorts of germ cell types (spermatogonia, spermatocytes, and spermatids) undergo incomplete cytokinesis and are retained as syncytia of synchronously differentiating cells conjoined by narrow intercellular cytoplasmic bridges. Mouse primary spermatocytes undergo meiotic prophase I in a syncytium of over 500 cells, and these bridges are maintained through the meiotic divisions and well into the later stages of spermiogenesis. These bridges enable the sharing of cytoplasmic constituents between neighboring cells ([Braun et al., 1989](#)). The exact roles and functions in spermatogenesis are unclear, but the intercellular bridges are thought to coordinate the spermatogenic progression of developing cohorts, and also to enable haploid spermatids to be “phenotypically diploid,” that is, if the male heterozygous for a mutation in a crucial haploid expressed gene such as a protamine, the spermatids bearing the mutant copy are rescued by obtaining mRNA from the genetically WT syncytium-mates ([Greenbaum et al., 2011](#)). Furthermore, knockout of a gene (*Tex14*) that is required for intercellular bridge formation causes arrest of spermatogenesis at the prophase I spermatocyte stage ([Greenbaum et al., 2006](#)). Thus, meiosis in spermatocytes requires some function of this structure, but that function remains unknown.

Another important intercellular interaction is that between germ cells and Sertoli cells. Intimate contact between germ cells and Sertoli cells is initiated when seminiferous cords are formed early in testicular morphogenesis. However, their proliferation/differentiation schedules are distinct after birth. In the mouse, Sertoli cells proliferate in the perinatal period, and their proliferation stops ~15 days after birth. Conversely, male germ cells become mitotically quiescent after populating the fetal gonad. Soon after birth they begin proliferating and migrate to the basal lamina of the seminiferous tubule, after which their proliferation slows they undergo differentiation into spermatogonia. During this pubertal development, Sertoli cells interact and, under androgen regulation, establish specialized cell–cell junctions that are the functional basis for the basal and adluminal compartments of the seminiferous epithelium. As a critical event of early meiotic prophase, germ cells pass through these junctions and exit the basal compartment to establish themselves in the adluminal compartment as primary spermatocytes ([Smith and Braun, 2012](#)).

Fig. 1 Male gamete development. The *double ended arrow* in the spermatogonia panel denotes that proliferating “transit-amplifying” spermatogonia may revert to stem cell status. Once a spermatogonium enters meiosis, it is irreversible. SSC, spermatogonial stem cell; BTB, blood testis barrier; N, chromosome number; C, DNA content. The *red dot* in the Meiosis I cell represents a chiasma (crossover).

What Makes Spermatocytes Unique?

Spermatocytes are the only cells in males that undergo meiosis, a specialized cell division process characterized by a single round of DNA replication followed by two rounds of chromosome segregation. These divisions produce four haploid spermatids from a single primary spermatocyte (Fig. 2). The reduction in ploidy is essential for gametogenesis in all sexually reproducing organisms.

Spermatocytes are “born” from a Type B spermatogonium that undergoes a final instance of DNA replication called premeiotic DNA replication. The cells are now called primary spermatocytes, which are formally in “prophase I” of the G2 stage of the meiotic cell cycle. Prophase I lasts several days, during which the defining events of meiosis occur, namely alignment (pairing) and synapsis (intimate attachment) of the homologous chromosomes, and genetic recombination. The process of recombination, namely the subset of recombination events called crossovers, occurs at least once on every chromosome pair, leading to an infinite number of potential chromosome constitutions in each haploid spermatid product. At the end of prophase I, primary spermatocytes undergo the first meiotic division (MI), which is “reductional” (homologous chromosomes segregate to daughter cells, not sister chromatids). The resulting two cells are called secondary spermatocytes, which immediately undergo the second meiotic division (MII), which is “equational” (sister chromatids segregate to daughter cells). The resulting cells (total of four from each original spermatocyte) are haploid round spermatids (Fig. 2). The following sections describe these events in greater detail.

Homologous Chromosome Synapsis in Spermatocytes

The events leading to MI require that chromosomes first pair in a process that is dependent upon homologous recombination. Following homolog recognition and initial alignment, homologous chromosomes then synapse via the assembly of a proteinaceous

Fig. 2 Reductional and equational meiotic divisions. The *black* and *blue* chromosomes at the top represent homologs, not sister chromatids. N, chromosome number; C, DNA content.

structure called the synaptonemal complex (SC). The process of retaining the homologs together (at a distance of ~ 100 nm), in the context of the SC, is termed synapsis. The SC, which is unique to meiosis, reinforces the process of meiotic recombination. The chromatin of meiotic chromosomes is arranged into a series of loops originating from the SC-defined meiotic chromosome axis. Only a small fraction of the DNA is actually in contact with the SC along its linear length, which spans each autosome in its entirety.

MI is subdivided into four main substages: prophase I, metaphase I, anaphase I, and telophase I. Each stage is identified by the major characteristic events, which allow the dividing cell to progress toward the completion of meiosis. Prophase I is the longest stage, because it involved so many intricate events. Prophase I is subdivided into five substages based on the appearance and dynamics of meiotic chromosomes. The chromosomes can be cytologically defined by the physical state of SCs (**Fig. 3**).

Fig. 3 Structure of synaptonemal complex (SC) during pachynema. SC, synaptonemal complex; LE, lateral element; CE, central element.

Chromosomes begin to condense during *preleptonema*. The SC assembly and homolog pairing follow this during *leptonema* (adjective = leptotene), which is particularly defined by the formation of immature SC fragments composed of two lateral elements (LEs) that begin forming along each chromosome. The LEs mature later into the axial elements (AEs). SYCP2 and SYCP3 are two major components of AE/LEs that create a bipartite structure along the bivalent axes. SYCP2 (but not SYCP3) serves as a linker between AE and the transverse filaments (TFs). The AE/LE coalign with cohesin cores (see below) and are connected by the TF, so that C-terminal end fastened to the LE and the other N-terminal to the central element (CE), which forms in later stages.

In *zygonema*, homologs begin to pair and CEs are deposited between the AE/LEs along the entire chromosome length. SYCP1 in mammals is a component of TFs, which is turn are a major component of the CE. There are many other proteins have been identified that associate transiently and provide stability to SCs. SYCP1 forms unstable homodimers by N-terminal self-associations and further require SC central element proteins 1–3 (SYCE1, SYCE2, and SYCE3) for stabilization and initiation of synapsis. These proteins are not only important for the structure of the SC in forming stable attachments between homologous chromosomes, but the axis proteins SYCP2/3, and also the HORMAD1 and HORMAD2 proteins, which bind only with unsynapsed chromosome regions of AEs are important for regulating recombination such that homologs, rather than sister chromatids, recombine (see below) (Rinaldi et al., 2017; Li et al., 2011; Shin et al., 2013). There are also other proteins that are important for synapsis, such as FKBP6, which are not discussed here (Noguchi et al., 2008).

During *pachynema*, synapsis occurs along the entire length of homologs and SCs are completely formed. This event allows close association between maternal and paternal axes. This is the stage when spermatocytes are fully prepared for recombination (described in sections below) between homologs. The physical connections established during this stage, as a consequence of cross-overs (chiasmata), are crucial for proper disjunction of homologous chromosomes to daughter cells at MI. They maintain physical attachment of homologs at the metaphase I plate. The onset of *diplonema* is described by the disassembly of the SC and homolog desynapsis. The final stage of prophase I is *diakinesis*, which quickly progresses into metaphase I.

Homologous Recombination (HR) in Primary Spermatocytes

HR is a mechanism, present in essentially all forms of DNA-based life, for repairing double stranded breaks (DSBs) in DNA. As indicated above, meiotic recombination is an essential and integral event in spermatocytes. The processes of stable homolog alignment, chromosome synapsis, and accurate MI disjunction are dependent upon HR. Since HR is a DNA repair mechanism, it requires generation of DSBs on the DNA during early prophase I. DSBs are generated by a topoisomerase type II-like protein, SPO11, and the action of this protein is essentially tantamount to meiotic initiation. These DSBs are nonrandomly distributed throughout the genome; they tend to cluster in discrete genomic regions called *hotspots*, and the locations of these hotspots are influenced in humans and mice by the action of the PRDM9 protein (Parvanov et al., 2010; Baudat et al., 2010). DSBs are processed to expose 3' overhanging ends that are bound by several enzymes, including recombinases called RAD51 and DMC1, which are homologs to bacterial RecA. These protein coated filaments conduct a "homology search" that ultimately ends with alignment to the allelic region of the homologous chromosome, invading the double helix of the homologous strand to form recombination intermediates. Ultimately these intermediates are resolved; ~90% of the time as "noncrossovers," and the remainder as crossovers.

Crossovers can be cytologically detected as structures called *chiasmata*. Chiasmata and cohesins along sister chromatid arms hold homologous chromosomes together during recombination and prior to their segregation in anaphase I. These processes occur by the end of prophase I, where *primary spermatocytes* undergo diakinesis and the first meiotic (reductional) division to produce two secondary spermatocytes, which divide equationally to generate the four haploid products (Fig. 2). Each spermatid is unique, the consequence of random combinations of recombination events in Prophase I and random segregation of recombinant homologs at the first meiotic division.

Meiotic Sex Chromosome Inactivation (MSCI) in XY Chromosomes

X and Y chromosomes in eutherian mammals are highly divergent in structure and gene content. In primary spermatocytes, these can synapse only through a small distal region of homology called as pseudoautosomal region (PAR). In pachynema, the paired XY chromosomes become sequestered into a defined heterochromatin-rich subdomain of the nucleus called the "sex body" (alternatively, the "XY body"). In this condensed state, the genes on the X and Y chromosomes are inaccessible to the transcriptional machinery, effectively causing chromosome-wide silencing, termed as "meiotic sex chromosome inactivation" (MSCI) (Handel et al., 1994). MSCI controls the unpaired regions of the X and Y and is critical for completion of meiosis in male mice. Experiments in mice and nematodes have shown that when either the X or Y chromosome is provided with a homologous pairing partner, it can form a synapsed bivalent that remains untouched by MSCI. These results established the sex chromosome *asynapsis* as the principal cause of MSCI. Upon entering pachynema, several proteins including BRCA1, TOPBP1, and ATR coat unsynapsed AEs of the sex chromosomes followed by their further spreading into the X and Y chromatin. The sex body chromatin is modified with specific histone marks associated with MSCI including H3K9me2, ubiquitylated H2A, and the phosphorylated histone variant of H2AX, γ H2AX. Together, these and other proteins enable MSCI (Hoyer-Fender, 2003).

Similar to MSCI, unpaired autosomes are also transcriptionally silenced by a process referred to as meiotic silencing of unpaired chromatin (MSUC) (Turner et al., 2005). Similar phenomena have been described in many organisms including eutherians,

marsupials, chickens, nematodes and fruit flies, and key features are conserved. In mammals, sites of asynapsis are associated with proteins that are components of DNA repair and DNA damage signaling machinery. Asynapsis triggers phosphorylation of many axis proteins, leading accumulation of the same protein and protein modifications that cause MSCI (Turner et al., 2004). These events ultimately trigger heterochromatinization and transcriptional silencing of unsynapsed regions.

Checkpoint and Genetic Quality Control Mechanisms in Spermatocytes

A fundamental charge of gametogenesis is to minimize the mutational load transmitted to offspring. Mutations and genetic aberrations have several forms, including single nucleotide changes, insertions/deletions, aneuploidy, and gross chromosomal rearrangements (GCRs). In vegetatively proliferating cells, errors in DNA replication are responsible for the majority of accumulated mutations. This is understandable given the task of duplicating a diploid genome consisting of 6 billion nucleotides. Whereas most mutations introduced during DNA replication entail single nucleotide changes and small indels associated with low complexity duplicated sequences, the mutagenic events to which meiotic cells are prone are more serious: aneuploidy and GCRs such as translocations and interstitial deletions. Gametic aneuploidy is the major cause of birth defects and spontaneous abortions in humans. Aneuploidy can occur during either MI or MII of meiosis, but the following discussion concentrates on the elaborate challenges to genome integrity in prophase I and the mechanisms to mitigate them.

As discussed earlier, proper chromosome disjunction at MI requires meiotic recombination, which in turn requires genetically-programmed DSBs. In a sense, these DSBs are a double edged sword; while essential for meiosis and fertility, they constitute a dangerous form of damage that can lead to gene disruption and GCRs. Under normal circumstances, the number of SPO11-induced DSBs is regulated so as to be sufficiently high to drive HR-driven chromosome synapsis, but sufficiently low such that all the DSBs can ultimately get repaired. Still, the system is not perfect. Accordingly, spermatocytes have adaptive mechanisms that render them highly sensitive to unrepaired DSBs and the presence of asynapsed chromosomes. The most prominent is the “pachytene checkpoint” that triggers apoptotic death of spermatocytes that fail to repair all DSBs, or which bear one or more asynapsed chromosomes. Mutant mice that are defective for DSB repair or synapsis die at Stage IV of the seminiferous tubule developmental cycle, equivalent to the mid-pachytene stage of meiosis (Barchi et al., 2005).

Experiments with mutant mice have identified MSCI and MSUC as being crucial processes in the pachytene checkpoint that prevent the production of chromosomally abnormal sperm. This is not immediately intuitive, but these mechanisms are essentially tied to conserved DNA damage response (DDR) pathways. Unsynapsed chromosomes or unrepaired DSBs activate canonical DDR components including the checkpoint sensor kinases ATM and ATR. BRCA1 and TOPBP1 act as cofactors promoting ATR activity in response to unsynapsed meiotic chromatin, which in turn phosphorylates histone H2AX. These events lead to meiotic silencing (MSUC for autosomes or MSCI in sex chromosomes). Because the same proteins are involved in sensing asynapsis and unrepaired DSBs, and some are present in limiting quantities, autosomal defects that trigger MSUC can weaken MSCI, causing apoptosis as described earlier. This disruption of MSCI is thought to constitute the major genetic quality control checkpoint in spermatocytes, although more canonical DDR signaling via the ATM signaling pathway is also active (Pacheco et al., 2015).

Glossary

Acrosome A membrane bound organelle closely applied to the surface of spermatids and spermatozoa. Formed by the Golgi apparatus of early spermatids, it is rich in hydrolytic enzymes and important for fertilization.

Axoneme The central portion of the sperm tail composed of a microtubular array with associated structural proteins.

Fibrous sheath The cytoskeletal structure along the principle piece of the tail. Glycolytic enzymes important for sperm metabolism are tightly bound to the fibrous sheath.

Manchette Appears in elongating spermatids as a sheath extending from the nucleus, surrounding the tail and disappearing during the late steps of spermiogenesis; involved in protein transport to the base of the axoneme.

Outer dense fibers Major cytoskeletal elements of the tail of elongated spermatids and spermatozoa. In the middle piece there are nine ODFs, one per axonemal doublet. In the principle piece of the tail only seven ODFs are present.

Introduction

As described in the section “Overview of Spermatogenesis,” building a sperm consists of the formation of spermatogonia from spermatogonial stem cells, mitotic divisions of the spermatogonia to form spermatocytes, two meiotic divisions of the spermatocytes that result in the formation of spermatids, and spermatid differentiation to form spermatozoa. The latter process, spermiogenesis, is the focus of this article.

The round spermatids that result from meiosis exhibit a remarkable transformation during spermiogenesis to become flagellated spermatozoa with extremely compact nuclei. During this process, the round spermatids undergo profound remodeling in sequential “steps” to form elongated spermatids. The steps are distinguished from each other by the specific structural changes that occur in the forming acrosome and the nucleus. In addition to morphological changes, there are molecular events that lead to the formation of the sperm acrosome, mid-piece and flagellum. The morphological and molecular changes that occur during spermiogenesis are critically important in achieving production of functional male gametes.

During the cellular transformation of haploid round spermatids to spermatozoa, major structural changes occur that include formation of the acrosome from the Golgi apparatus, nuclear elongation, chromatin condensation, axoneme formation triggered by the centriolar complex, and assembly of sperm-specific cytoskeletal elements including the mitochondrial sheath surrounding the axoneme. The distinct steps of spermiogenesis identified in man (Oko and Clermont, 1999) are depicted in Fig. 1. Recently,

- Changes that transform spermatids into spermatozoa
 - discarding excess cytoplasm & growing tails

Fig. 1 Depiction of transition steps from round spermatid to elongated spermatozoan. From Oko, R and Clermont, Y 1999. Spermiogenesis. *Encyclopedia of Reproduction*, Vol. 4 Pro-Z, pp. 602–609. Cambridge, MA: Academic Press.

high-resolution light microscopy (HRLM) has enabled improved morphological identification of all germ cells (spermatogonia, spermatocytes, spermatids) in the human testis (Nihi et al., 2017). This approach has led to a highly reliable way to identify the events of spermatogenesis in man. Precise staging of germ cells is important for predicting causes of aberrant spermatogenesis and infertility.

Spermiogenesis

Spermatid development, or spermiogenesis, extends over 22.7 days in rats and 21.6 days in humans. Formation of the acrosome is a key event in spermatid development. The acrosome is a membrane-bound organelle on the surface of the nuclei of spermatids and spermatozoa. Acrosome formation begins in the early spermatid by coalescence of proacrosomic vesicles to a single large vesicle which tightly adheres to the nuclear membrane. The acrosomal vesicle is rich in hydrolytic enzymes that are released during the acrosome reaction, a critical step in fertilization that enables sperm penetration of the zona pellucida of the egg.

DNA Compaction

Morphological remodeling of the spermatid involves nuclear elongation and chromatin condensation, producing the species-specific form that is characteristic of the sperm head. During these processes, there is reorganization of the haploid genome and compaction of DNA. Human sperm chromatin undergoes a complex remodeling in which histones are replaced by protamines during a regulated transition that involves histone modifications (H1t histone is modified or lost) as well as intermediate and temporary replacement of the histones by sperm-specific transition nucleoproteins TP1 and TP2. Chromatin compaction is influenced by TP1 and TP2. These transition proteins are then replaced late in spermiogenesis by arginine and cysteine-rich protamine. Protamine polymorphisms can lead to compaction defects, increased susceptibility to DNA damage, and infertility. The replacement of most histones by protamine 1 (PRM1) and protamine 2 (PRM2) facilitates a high order of chromatin packaging necessary for normal sperm function, and may also be required for DNA silencing and imprinting changes (Carrell et al., 2007).

Epigenetic modifications, characterized by DNA methylation, histone substitutions, and chromatin remodeling, also are important regulators in spermiogenesis. Several genes in the germinal epithelium are regulated through epigenetic mechanisms, and there have been suggestions of an influence of epigenetics on spermatogenesis. Epimutations (often hypermethylation) in several genes (e.g., MTHFR, PAX8, NTF3, SFN, HRAS, JHM2DA, IGF2, H19, RASGRF1, GTL2, PLAG1, D1RAS3, MEST, KCNQ1, LIT1, SNRPN) have been reported to be associated with poor semen parameters or male infertility. Recent reports suggest that epigenetic modifications in mature sperm may also have effects on embryo development (Carrell and Hammoud, 2010).

The Manchette (Acrosome and Tail Formation)

Spermiogenesis also involves the elongation of spermatids and removal of excess cytoplasm, as well as the formation of the acrosome and tail. Protein transport during spermatid elongation is required for the formation of the sperm tail and acrosome, and for shaping of the sperm head. Proteins are transported to the developing sperm head and tail by the manchette, a microtubular structure that surrounds the elongating spermatid head and that is present only during spermatid elongation, and by the axoneme, a microtubule-based cytoskeleton composed of nine pairs of microtubules doublets and two central microtubules that is the core structure of the sperm tail depicted in Fig. 2 from Chen et al. (2016).

In the mouse and human, the manchette is first seen first in mid-spermiogenesis (step 8 in the mouse, and step 5 in the human; see Fig. 1). It forms between the perinuclear ring that surrounds the nucleus and the elongating sperm axoneme. Much is now known about the assembly, disassembly and function of the manchette, and the roles of these processes in spermatid head-shaping and sperm tail formation, including the molecular events that are involved (Lehti and Sironen, 2016). Among the molecular players is SPEM1, a protein expressed only in developing spermatids (Bao et al., 2011). Inactivation of Spem1 in mice has been shown to result in deformed spermatozoa. UBQLN1 has been identified as a SPEM1-interacting partner (Bao et al., 2010). UBQLN1 and SPEM1 have been co-localized to the manchette of elongating spermatids. UBQLN1 functions through binding and directing poly-ubiquitinated proteins to the proteasome for degradation. Consequently, the interactions shown to occur between UBQLN1 and SPEM1 suggest a role for UBQLN1 in regulating protein ubiquitination during spermiogenesis. Ran-binding protein 17 (RANBP17) also was identified as an interacting partner of SPEM1 (Bao et al., 2011). RANBP17 was shown to localize to the XY body of primary spermatocytes, later in spermatogenesis to the nuclei of round spermatids (steps 1–7), and finally, together with SPEM1, to the manchette of elongating spermatids (steps 8–14). As a member of a protein family involved in nucleocytoplasmic transport, RANBP17 has been suggested as possibly playing a role in sex chromosome inactivation during meiosis and/or in intramanchette transport during spermiogenesis. Interactions between RANBP17 and SPEM1 suggest that SPEM1 might function in RANBP17-mediated nucleocytoplasmic transport.

Observations by electron microscopy have revealed rod-like elements linking the manchette microtubules to the nuclear membrane (Russell et al., 1994). The manchette appears to be connected through a protein complex called the LNC complex (linker

Fig. 2 Formation of Manchette during spermiogenesis. From Chen, S.R. et al. 2016. *Cell Death & Disease* 7(11), e2472.

of nucleoskeleton and cytoskeleton). Two LINC complexes have been identified during spermatid elongation: the SUN3/Nesprin 1 protein complex, which has been shown to connect the manchette to the nucleus; and SUN1/Nesprin 3 which, with SUN3/Nesprin, has been localized to sites at which manchette microtubules contact the nuclear envelope. It has been suggested that the LINC complex may be involved in nuclear shaping (Göb et al., 2010; Calvi et al., 2015).

Successful sperm production requires proteins and protein complexes to be transported to the correct assembly sites during sperm tail formation. However, the exact roles of microtubule and actin-based delivery complexes remain uncertain. Some proteins appear to be transported through the manchette to the base of the developing sperm tail. However, not all sperm-tail proteins have been localized to the manchette, raising the prospect that different, more complex, mechanisms for protein storage and transport may be involved in sperm formation (Lehti and Sironen, 2016). Functional studies will provide a more complete understanding of the mechanisms involved in constructing a fertile sperm, important for developing therapies for male infertility and perhaps for identifying targets for a reversible male contraceptive technology.

Formation of the Tail

Sperm tail formation is an important step in remodeling the spermatid. Early in spermiogenesis, a pair of centrioles migrates toward the nucleus and eventually binds to it (Fig. 1). Formation of the central component, the axoneme, is initiated by one of the pair. The axoneme is comprised of a characteristic “9 + 2” microtubule arrangement, dynein arms, radial spokes, and the nexin-dynein regulatory complex (N-DRC) (Inaba, 2011). As noted above, there is an intimate association of the nucleus and manchette for delivery of essential proteins. It currently is hypothesized that proteins are moved by intramanchette transport to the base of the sperm tail and to the developing sperm tail itself by intraflagellar transport. Outer dense fibers and a fibrous sheath appear shortly after the axoneme completes its growth. The T-complex-associated-testis-expressed 1 (TCTE1) evolutionarily conserved axonemal protein localizes to the nexin-dynein regulatory complex and is testis-enriched in its expression, with its mRNA appearing in early round spermatids and protein localized to the flagellum. TCTE1 is 498 aa in length with a leucine rich repeat domain at the C terminus. Recent studies (Castaneda et al., 2017) revealed that knockout of Tcte1 results in male sterility. Tcte1-null spermatozoa show aberrant motility. Although the axoneme is structurally normal in Tcte1 mutant spermatozoa, Tcte1-null sperm demonstrate a significant decrease of ATP, which is used by dynein motors to generate the bending force of the flagellum. As the authors note, these data provide a link to defining the molecular intricacies required for axoneme function, sperm motility, and male fertility as discussed below.

Sperm Tail Enzymes

While structure and motility are relatively well-defined, the functions of the outer dense fibers and fibrous sheath are less clear. Most of the glycolytic enzymes responsible for meeting sperm energy requirements are tightly bound to the fibrous sheath. These enzymes include a sperm specific form of glyceraldehyde phosphate dehydrogenase (GAPDH-S) and lactate dehydrogenase A (LDHA). The most abundant sperm specific protein, LDHC, is cytosolic and distributed throughout the sperm tail. Many species of spermatozoa, including mouse and human, generate ATP by aerobic glycolysis to satisfy their energy requirements even though the mid-piece houses the mitochondria that in most cells are the efficient energy producers. Both GAPD-S and LDHC have been proven to be required for sperm function by targeted disruption of the cognate genes. When and how these sperm proteins become distributed to the sperm tail is not obvious. For example, the *Ldhc* gene is transcribed and translated prior to and during meiosis, whereas *Gapds* may be transcribed in spermatocytes but not translated until meiosis is completed. Clearly, it would be expected that the transcriptional apparatus is disabled in haploid cells. To date, most of the testicular mRNAs known to be translationally regulated are initially transcribed in postmeiotic cells. There are numerous studies in the last decade showing that mRNA is stored (often referred to as “masked mRNA”) and is translated during spermiogenesis (Xu and Hecht, 2008). Additionally, there are examples of post-transcriptional modifications of gene products during spermiogenesis that are beyond the scope of this article. Generally speaking there are changes in transcription and translation throughout spermatogenesis, including spermiogenesis.

Mitochondria Migration

In elongating rodent and human spermatids, the mitochondria migrate toward the forming tail as the manchette appears (Fig. 1). The mitochondria assemble along outer dense fibers, between the neck and the annulus, and assemble into a spiral structure in what becomes the mid-piece of the sperm tail. The length of the sperm tail is species specific.

Intercellular Bridges

Intercellular bridges connect all the spermatids originating from the same stem cell, a consequence of the incomplete cytokinesis of spermatogonia during mitosis and of spermatocytes during meiosis. Disruption of the intercellular bridges can cause male infertility. The importance of intercellular bridges is clear. Thus, movement of molecules among haploid cells is made possible by intercellular bridges, and this movement is likely to be involved in the sharing of mRNAs among germ cells. This sharing, in turn, is important for sperm production because numerous essential proteins are encoded on sex chromosomes (Kim et al., 2015).

Spermiation

When the remodeling process of the spermatid has been completed, elongated spermatids are ready for release from the germinal epithelium. The action of the steroid hormones estrogen and androgen, which are known to control transcription in various reproductive and nonreproductive tissues, are important for the control of sperm release from the seminiferous epithelium (spermiation). Spermiation is characterized by extensive remodeling of actin filaments and endocytosis. There is evidence suggesting that genes regulated by estrogen and androgen may in some way be involved in actin remodeling and endocytosis.

Summary

This outline of spermiogenesis briefly describes the exquisitely complex structural and molecular intracellular changes required for producing and shaping what is destined to become a functional male gamete. Other chapters will describe the involvement of Sertoli cell–germ cell interactions, and will provide further details about the contribution of Leydig cells in the interstitium. These interactions too are essential for completing the highly-ordered process necessary for sperm production and thus survival of the species.

The First Wave of Spermatogenesis

Ricardo D Moreno, Pontifical Catholic University of Chile, Santiago, Chile

Introduction

The first wave of spermatogenesis can be defined as every process of division and differentiation undergone by a germinal cell from the spermatogonium (a stem cell), until the production of the first spermatozoa, which signals the beginning of male fertile life. In rodents, this wave, is completed within the first 6 weeks of life and is followed by successive waves, which overlap each other ensuring the continuous production of spermatozoa throughout the male fertile life.

Since the first wave of spermatogenesis is a milestone in the male reproductive life it has certain characteristics of its own that are not shared with the spermatogenesis in the adult and makes it worth to study.

Spermatogenesis in the Adulthood

Mammalian adult testes have two important functions: one is endocrine, since they are the main source of testosterone; the second is the production of male gametes, spermatozoa. The process by which sperm is formed is known as spermatogenesis, and occurs within tubular structures—the seminiferous tubules. These tubules contain two types of cells—somatic cells (named Sertoli), and germ cells (those that will form spermatozoa)—and in the interstitial compartment, a third cell type can be found—the Leydig cell—which is the major source of testosterone. Once the adult stage is reached, spermatogenesis may be continuous, as in humans, but it can also occur only at certain periods of the year, as in Siberian hamsters.

Spermatogenesis in adults can be divided into three phases:

1. In the Proliferative Phase, a group of diploid stem cells (called spermatogonia) which has the ability of self-renewal, that is, to divide constantly, begins the path of spermatogenesis. In order to increase their number, they start to divide and after the sixth cell division, approximately, they enter into meiosis, which marks the next stage of spermatogenesis.
2. The Meiosis is a type of cell division that occurs only in the testes and ovaries and originates four haploid cells. During meiosis, the recombination process ensures that every haploid cell that is produced has a unique combination of genes and thus guarantees the diversity of the progeny. Cells in meiosis are known as spermatocytes, which in turn can be subdivided according to the different substages of meiosis.
3. During the Differentiation Phase or Spermiogenesis, haploid cells (now called spermatids) experience morphological, biochemical, and physiological changes such as modification of the shape of the head, flagellum development and cytoplasm remodeling, hence transitioning into a spermatozoon. According to its morphology and degree of differentiation it is possible to unveil two types of spermatids: round and elongated.

As mentioned above, spermatogenesis is continuous throughout the male fertile life. Given this, in an adult testis we can find all the previously described germ cell types at the same time, which, as we will see, does not occur during the first wave of spermatogenesis since they are sequentially formed as the differentiation progresses are unfold.

Spermatogenesis begins very early in fetal stage (De Felici, 2000). During development, the so-called primordial germ cells or PGCs migrate to the mesonephros, where they meet with somatic cells (the future Sertoli cells) around embryonic day 12.5. When these two types of cells are brought together, they arrange the seminiferous cords, that is, the precursors of the seminiferous tubules without lumen. At this stage, germ cells (called pro-spermatogonia or gonocytes) enter into a proliferative resting phase, nondividing until puberty, where proliferation reinitiates and the first wave of spermatogenesis begins.

The First Wave of Spermatogenesis or the Awakening of the Force

The onset of the first wave of spermatogenesis is marked by the proliferation of prespermatogonia or gonocytes, which begins in prepuberal males (Fig. 1).

At this step, the seminiferous cords are populated only by Sertoli cells and gonocytes are located in the lumen. From a morphological point of view, gonocytes, or prespermatogonia, are cells with a large, round nucleus placed in the center of the seminiferous cords, whereas spermatogonias are elongated cells with prominent nucleoli and situated at the periphery of the cords. The differences regarding the location and shape of these cells are product of important changes in the expression of multiple genes that control cell proliferation and differentiation. In the mouse, this transition from gonocytes to spermatogonia occurs during the first 3 days of life, whereas in the human it takes several weeks or months and occurs during the fetal life (Fig. 1).

Underlying this differentiation process are various types of signals that are received by the gonocytes and eventually determine their differentiation. In the mouse, 1–2 days after birth, gonocytes begin to proliferate and migrate to the periphery of the seminiferous cords. This proliferation is induced by molecules or factors secreted by Sertoli cells such as platelet-derived factor (PDGF-BB), 17- β -estradiol, and retinoic acid (Manku and Culty, 2015). This is one of many examples that we can find where there is a paracrine

Fig. 1 Comparative timeline of the first wave of spermatogenesis. The first wave of spermatogenesis begins a few days after birth in both mice and rat. The timeline on the left indicates the age at which different types of germ cell differentiations can be detected according to their degree of differentiation. The photos show sections of testicles of 30 and 10-day-old rats where the arrows indicate the cell types that can be found in each of the respective cases. Bar = 50 μ m.

communication between the Sertoli and germ cells. Once spermatogonia arise, they begin to proliferate and accommodate in pairs or rows, one after another, which reflects different subtypes (A1, A2, A3, A4, In and B) each one with a greater commitment degree to differentiation. The spermatogonia subtype-B is the one that effectively enters meiosis. Among the signals involved in this process, the retinoic acid, which is a derivative of vitamin A that is produced by the Sertoli cell, is quite relevant since germ cells contain proteins (receptors) that are capable of binding to it and thus induce the expression of specific genes (Manku and Culty, 2015). It is interesting to note that retinoic acid has also been implicated in the induction of meiosis in females, a process that occurs during fetal life, hence indicating that it is a conserved mechanism between males and females. Spermatocytes in leptotene, which is the first stage of meiosis, initially appear in 10 days-old mice and 9–12 days-old rats and continue their differentiation program and progress through the following stages of meiosis (Fig. 1). Once these cells have completed meiosis they give rise to the haploid or round spermatids (haploid cells), which can be first detected in 20 days-old mice and 26 days-old rats. Then, around the 35th and 45th day in mice and rats, respectively, round spermatids experience spermiogenesis (the final stage of differentiation) resulting in testicular spermatozoa (Figs. 1 and 2). Eventually, these cells detach themselves from the other germ cells and are released into the

Fig. 2 Relative amount of different germ cell types according to the age of development. The graph shows the relative abundance of spermatogonia (blue line), spermatocytes (green line), and spermatids (round and elongated, red line), according to the age in rat. In the early days of age there is a significant increase in spermatogonia, which decreases around 12 days because they start to enter the meiosis and spermatocytes are able to be observed. Subsequently, these cells complete meiosis and spermatids are produced, becoming the most abundant cell population in the seminiferous tubules. Graph data was adapted from Yang, Z.W., Wreford, N.G. and de Kretser, D.M. (1990). A quantitative study of spermatogenesis in the developing rat testis. *Biology of Reproduction* 43, 629–623.

lumen of the seminiferous tubules, and transported to the epididymis, where they undergo a maturation process becoming ready to be ejaculated. It is important to mention *in vitro* studies have shown that spermatids formed during the first wave of spermatogenesis are functionally active and capable of generating viable embryos, although these are produced at a much lower rate than those from spermatids formed during adult spermatogenesis (Miki et al., 2004). These results have been achieved using assisted reproduction techniques where spermatids are injected into mouse oocytes (since they are immobile), and the embryos produced *in vitro* are subsequently transferred to recipient females.

From a technical point of view, morphology of the biology of the first wave of spermatogenesis due to the sequential apparition of the different germ cell types has been very useful when studying spermatogenesis, since it is possible to take advantage of the sequential apparition of specific germ cell types and design more efficient isolation procedures using testis (mice or rats) of specific ages. That is, if we want to isolate round spermatids, we should use testicles of a 20 days-old specimen, while if we wanted to isolate spermatogonia we should use a 6–8 days-old one.

While the first wave of spermatogenesis progresses, Sertoli cells also suffer alterations, especially in shape and function (Holsberger et al., 2005). A few days after birth, these cells, along with germ cells, begin to proliferate until around the 30th day in rat. The cessation of proliferation of Sertoli cells is associated with its differentiation process. One of the critical events in this process is the generation of the so-called hemato-testicular barrier, which is the product of tight junctions between the Sertoli cells in a way that prevent the entering of the majority of soluble plasma compounds into the seminiferous tubules. These junctions are formed developmentally right after the differentiation of the first spermatocytes into zygotene (the stage that follows leptotene), and in this way isolate all the subsequent germ cells from the rest of the body (Morales et al., 2007). Thus, Sertoli cells provide nutrients and support germ cell differentiation until the spermatozoa are released into the lumen of the seminiferous tubule. Studies in rat indicate that the developing of this barrier begins between the 15th and 16th day and is completed at the 18th day (Fig. 3). On the other hand, the formation of the lumen within the seminiferous cords, which is another parameter of Sertoli cells differentiation, begins to be observed as early as the 10th day in mouse (Russell et al., 1989). The number of seminiferous tubules increases rapidly and at the 20th day almost all the cords have been transformed into seminiferous tubules (Fig. 3). At the same time, the size of the lumen progressively increases during the first wave of spermatogenesis and in mouse it reaches that of the adult at the age of 50 days. (See Fig. 4.)

Even though the general process between the first wave of spermatogenesis and the one observed in the adult are similar, there are some differences between them and it may be related to the multiple developmental changes that are observed during the spermatogenesis. One important difference is that in the former, the type of germ cell that can be found will depend on the age of the specimen, while in the latter, all types of germ cells coexist at the same time. Some authors have reported that the kinetics of the first wave of spermatogenesis in the mouse are similar to the ones in the adult but others have shown that it is about 20% faster than the adult, at least in the mouse (Kluin et al., 1982). This difference in velocity normalizes at 35 days of age, when, in the mouse, the first wave has already ended and spermatogonia begin to produce the following waves of differentiation (spermatogenesis). One of the possible causes of this difference in sperm production velocities may be due to the very origin of spermatogonia, which seems not to be exactly the same as in adults. As we have seen, spermatogonia are produced from the gonocytes, which migrate from the lumen and adhere to the walls of the seminiferous tubules and form the spermatogonial stem cells (SSC). In the adult, these cells express specific markers such as neurogenin-3 and are source of all spermatogonia. However, there are data, in the mouse, showing that the

Fig. 3 Relationship between Sertoli cell differentiation and germ cell apoptosis according to the age of development. The graph shows that from 10 days of age some seminiferous cords with lumen can be observed, which is indicative of the beginning of the differentiation of the Sertoli cell and the seminiferous tubule formation. This is a quick process and it is concomitant with the progressive increase in diameter of the lumen that reaches adult levels of around 45 days of age. Another important event in the differentiation of the Sertoli cell is the formation of the blood-testis barrier (yellow bar), which occurs just before the massive wave of apoptosis in the germinal cells (red bar). The data in this chart are adapted from Russell, L.D. (1978). The blood–testis barrier and its formation relative to spermatocyte maturation in the adult rat: A lanthanum tracer study. *The Anatomical Record* **190**, 99–111; Russell, L.D., Bartke, A. and Goh, J.C. (1989). Postnatal development of the Sertoli cell barrier, tubular lumen, and cytoskeleton of Sertoli and myoid cells in the rat, and their relationship to tubular fluid secretion and flow. *The American Journal of Anatomy* **184**, 179–89; Moreno, R.D., Lizama, C., Urzúa, N., Vergara, S.P. and Reyes, J.G. (2006). Caspase activation throughout the first wave of spermatogenesis in the rat. *Cell and Tissue Research* **325**, 533–540.

Fig. 4 Different ways of viewing cells in apoptosis. The figure shows four different techniques through which cells can be seen and quantified in apoptosis. In a testicle cut, which can be stained with a combination called PAS-hematoxylin, cells in apoptosis can be osseous (arrows). On the other hand, they can be seen by another technique called TUNEL that detects DNA rupture. This technique can be used with dyes (brown cells) or fluorescence (green cells). Since the tissue cannot be seen in this technique, a circle indicating the seminiferous tubule has been superimposed. During apoptosis caspase-3 is activated which can also be detected using a specific antibody (brown cells, arrows). Black bar = 100 mm.

first wave of spermatogenesis comes from a group of gonocytes and not from the SSC population, suggesting that they do not have exactly the same origin as the spermatogonia that form in the adult, which would explain the aforementioned differences (Yoshida et al., 2006).

Apoptosis in the First Wave of Spermatogenesis

Apoptosis is a type of programmed death in which the cell begins a genetic program to “commit suicide.” This genetic program includes several types of genes, and has been observed in different organisms being fundamental in the development of organs and tissues. In the case of the first wave of spermatogenesis, it has been observed that there is a massive germ cell death in both rat and mouse, occurring in 20–25 days-old rats and 18–20 days-old mice (Moreno et al., 2006). This massive germ cell death during the first wave has not been observed in other species such as human or ruminants, mainly due to the technical limitations and the limited biological material available during this specific developmental window. In the case of rats and mice, most of germ cells that die during this period are spermatocytes in the stage of pachytene, although some authors have also observed that some spermatogonia also enter into apoptosis (Rodriguez et al., 1997). It is interesting that this massive event of cell death occurs immediately after the formation of the hemato-testicular barrier (Fig. 3), suggesting that it is possible that the differentiation process of the Sertoli cell is in some way linked to the death of germ cells. It is interesting that within the whole set of genes known to be involved in apoptosis, there are some of them that are more important or that participate almost exclusively in apoptosis of germ cells. Among these genes is BAX, whose deletion (knockout) stops the first wave of spermatogenesis at the same stage where the apoptosis is observed, that is to say the stage of spermatocytes in pachytene (Knudson et al., 1995). These mice are therefore infertile since they do not produce spermatozoa. Another interesting gene is BCL-W, which has an antiapoptotic function, that is, it prevents apoptosis (Meehan et al., 2001). Genetic studies in which this gene has also been deleted (knockout) interestingly show that the first wave of spermatogenesis proceeds normally, but that adults are infertile due to a massive germ cell apoptosis. This is because during the first wave of spermatogenesis at least two other antiapoptotic genes (*Bcl-2* and *Bcl-XL*) are expressed, mainly in spermatogonia, whereas in the adult stage only *Bcl-w* is detected (Meehan et al., 2001). Thus, by deleting *bcl-w*, its function is compensated by the presence of *Bcl-2* and *Bcl-xl* during the first wave of spermatogenesis, which does not occur in the adult. These

results indicate that the regulation of apoptosis during the first wave of spermatogenesis and in the adult, are different and that this process is important for the production of spermatozoa.

The Hormonal Control of the First Wave of Spermatogenesis

Central to the production of spermatozoa and the progression of spermatogenesis is the hormonal control that is exerted on this process by the endocrine system. The production of testosterone in the male occurs mainly in Leydig cells, which are formed during the fetal stage 12.5 days of gestation in the mouse and between 7 and 14 weeks in the human (Svechnikov et al., 2010; O'Shaughnessy, 2014). Very soon after birth, the hypothalamus–pituitary gland gonad (HPG) axis is activated, which is reflected in an increase in testosterone sustained up to adult levels. That is, the release of testosterone is controlled by the luteinizing hormone (LH) produced by the pituitary, which in turn is regulated by the hormone GnRH released by the hypothalamus. This increase in testosterone production is critical for the onset and development of puberty, but it is also known that, at least in humans, there is a transient increase in testosterone levels in 2–3 months old children, which is called the “mini puberty” (Svechnikov et al., 2010; Li et al., 2015). Several genetic studies have been very valuable to study the contribution of various hormones in the progression of spermatogenesis, and in particular the first wave of spermatogenesis. For example, it is known that the generation of PGCs, their migration, differentiation in prespermatogonia (gonocytes), and formation of seminiferous cords occurs before maturation of the HPG axis, therefore these stages are not under control of this axis. This is also seen in mutant mice that do not produce GnRH (*hpg* mice) or in knockout mice for the receptors of the hormones FSH, LH or testosterone (Singh et al., 1995; O'Shaughnessy, 2014). In these experimental models, it has been observed that the first wave of spermatogenesis can be initiated and germ cells can reach meiosis, although there is a strong decrease in the number of germ cells as early as 5 days of life, compared to wild, suggesting an hormonal control of testosterone during this period. In addition, recent data suggest that, in the mouse, “mini-puberty” appears to coincide with a rise in FSH levels (Li et al., 2017).

Experimental evidence suggesting that both FSH and testosterone act by modulating massive apoptosis during the first wave of spermatogenesis comes from two lines of evidence. The first evidence emerges from experiments in which the exogenous administration of testosterone reduces the first wave of apoptosis (Rodriguez et al., 1997). The second group of evidence rises from the data obtained using KO mice for the FSH receptor and androgen receptor (total or only in Sertoli cells), which show that in these mice there is an exacerbated apoptosis of germ cells around 20–25 days of age relative to controls (O'Shaughnessy, 2014; Shiraishi and Matsuyama, 2017). Together these data indicate that both FSH and androgens, in particular testosterone, protect germ cells from apoptosis.

In addition, from the effects described in apoptosis of germ cells during the first wave of spermatogenesis, data indicate that mice lacking the androgen receptor gene in Sertoli cells are infertile due to the absence of spermatids. It is interesting that this same phenotype is observed in KO mice for the hormone receptor LH, indicating that even from the first wave of spermatogenesis, testosterone is fundamental for survival, and differentiation of haploid cells (spermiogenesis). Several studies have shown that the receptor for testosterone belongs to the family of steroid receptors and is mainly located in the nucleus of Sertoli, Leydig, peritubular (germinal cells surrounding the seminiferous tubules), and germinal cells. However, deletion of the androgen receptor in germ cells or peritubular cells has no effect on the fertility or progression of spermatogenesis of these mice (Wang et al., 2009). This suggests that the main effect of testosterone on spermatogenesis is exerted indirectly through the Sertoli cell.

In addition to testosterone and FSH, there is evidence that other hormones may also exert regulatory function during the first wave of spermatogenesis. The role of estrogen in spermatogenesis has been very controversial, but germ and Sertoli cells express the two isoforms of the estrogen receptor. In addition, the testis expresses the enzyme CYP19A1 (aromatase) which converts testosterone into estradiol (Carreau and Hess, 2010). The transcript for this enzyme can be detected in Sertoli cell and spermatogonia from 10 days-old rat onward. Mice KO for the estrogen receptor (alpha subunit) or overexpression of the *Cyp19A1* gene, are fertile and do not show major alterations in the first wave of spermatogenesis suggesting that this hormone may regulate spermatogenesis but it is dispensable for the normal progression of the first wave. On the other hand, it has been shown that the differentiation of Sertoli cells depend upon thyroid hormones (Holsberger et al., 2005). In fact, inhibition of T3/T4 production (hypothyroidism) in the neonatal rat impairs testicular growth, germ cell maturation, seminiferous tubule formation and other differentiation processes. In addition, it delays and increases the rate of germ cell apoptosis during the first wave of spermatogenesis (Silva et al., 2011). Therefore, the first wave of spermatogenesis is hormonally regulated at multiple levels.

Spermatogonial Response to Somatic Cell Interactions

Tessa Lord and Jon M Oatley, Washington State University, Pullman, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

The spermatogonial pool is diverse, however can be divided into two primary populations; the undifferentiated and differentiating pools. The spermatogonial stem cells (SSCs) are the undifferentiated self-renewing reservoir that facilitate continual sperm production from the time of puberty throughout the life of the adult male. Along with the SSCs, progenitor spermatogonia are also considered to be part of the “undifferentiated” population, however, can no longer self-renew and instead undergo transit-amplifying mitotic divisions to achieve clonal expansion. For the most part, it is accepted that progenitor spermatogonia in the undifferentiated pool exist as pairs or chains of up to 16 cells long, interconnected by intercellular bridges (referred to as A_{paired} or A_{aligned} respectively), while the SSCs are considered to be a subset of the A_{single} population (reviewed by Lord and Oatley, 2017). Progenitors also differ functionally from SSCs in that they are responsive to the differentiating signal in the testis; retinoic acid (RA). Thus, following the RA pulse that occurs every 8.6 days across the seminiferous epithelium of the mouse, the majority of progenitors will transition from type A (undifferentiated) to type A1 (differentiating) spermatogonia. This transition is immediately followed by further transit-amplifying mitotic divisions that accompany the formation of A2, A3, A4, intermediate, and finally type B spermatogonia. The type B spermatogonia are those which are poised to enter meiosis as preleptotene spermatocytes; thus beginning the journey to production of haploid male germ cells with the capacity to fertilize an egg.

Fate decisions within the spermatogonial population require tight regulation to ensure maintenance of the germline and optimal fertility. For instance, the decision between maintenance of the SSC population versus transition into a progenitor state; or the decision for progenitors to continue in an undifferentiated state versus commitment to differentiation; must be controlled to prevent exhaustion of the reservoir from which spermatogenesis arises. Extrinsic cues from the surrounding environment are instrumental in ensuring such regulation of these distinct spermatogonial populations. These cues primarily originate from the somatic cells in the testes. Somatic cells that are known to interact with the spermatogonial population exist both within the seminiferous tubules themselves, alongside the spermatogonia; i.e., Sertoli cells, but also exist on the outer of the seminiferous tubules; such as the androgen-producing Leydig cells that reside in the interstitial space, the peritubular myoid cells (PMCs), macrophages, and vascular cells (the orientation of these cells in the testis is diagrammatically represented in Fig. 1). Somatic cells primarily influence spermatogonial populations via the production of growth factors, the majority of which have been characterized to be important for driving self-renewal in SSCs, and maintenance of the undifferentiated population. However, depending on the stage of the seminiferous cycle, the same somatic cells that secrete factors required for maintenance of the SSC population can also facilitate the RA-driven transition of a subset of undifferentiated progenitors into differentiating spermatogonia; depicting the intricate and dichotomous role of these cells in terms of their interaction with the spermatogonial population. In this article we will provide an overview of somatic interaction with the spermatogonial population; examining the origins and actions of growth factors known to stimulate maintenance of the undifferentiated population, and also the production and degradation of RA within the seminiferous tubules to regulate the differentiating transition.

Somatic Cell Interaction With the Undifferentiated Spermatogonial Pool

Perhaps the most extensively studied somatic cell-spermatogonial interaction is the stimulation of SSC maintenance and self-renewal by growth factors produced by Sertoli cells in the SSC niche; particularly Glial cell-line derived neurotrophic factor (GDNF) and fibroblast growth factor 2 (FGF2) (Fig. 1). The SSC niche is thought to exist as a microenvironment at the basement membrane of the seminiferous epithelium, on the outer of the blood-testis barrier. This “open niche” is thought to be populated by the entire undifferentiated spermatogonial population, and true understanding of how SSCs and progenitor spermatogonia behave differently in the microenvironment remains to be determined. However, the action of GDNF on the SSC population is particularly well understood, with this growth factor exerting its effects via the GFRA1/RET receptor to stimulate PI3K/AKT signaling (Oatley et al., 2007) and upregulate expression of transcription factors known to be important in SSC maintenance and self-renewal, such as ETS variant 5 (*Etv5*), B-Cell CLL/Lymphoma 6B (*Bcl6b*) (Oatley et al., 2007) and Inhibitor of DNA binding 4 (*Id4*) (Oatley et al., 2011). As such, supplementation of GDNF into culture medium has been shown to directly stimulate self-renewal of SSCs in primary spermatogonial culture (Kubota et al., 2004), and further, although GDNF, GFRA1 and RET null mice do not survive into adulthood (Schuchardt et al., 1994; Moore et al., 1996; Pichel et al., 1996; Enomoto et al., 1998), GDNF^{+/-} mice exhibit severe impairments in proliferation of the spermatogonial population (Meng et al., 2000). Although FGF2 supplementation of culture media also influences SSC proliferation, in the absence of GDNF, FGF2 alone is not sufficient for SSC maintenance (Kubota et al., 2004). Based primarily on the outcomes of in vitro studies, GDNF and FGF2 concentration within the niche is thought to be critically important for regulation of the undifferentiated population in vivo. However, it has become apparent that growth factor production by somatic cells *outside* the niche can also directly influence the undifferentiated pool; as well as indirectly influence spermatogonial populations via interactions with other somatic cells. As the SSC niche has been covered extensively in another

Fig. 1 Somatic cell interactions with spermatogonia. Top: Somatic cells in the testes produce growth factors to drive self-renewal of SSCs and maintenance of the undifferentiated spermatogonia population. These growth factors include GDNF, FGF2, CSF1 and LIF. Middle: Key depicting cell types in diagram. Bottom: Somatic cells regulate differentiation of transit amplifying progenitor spermatogonia by controlling synthesis (RDH, ALDH) and degradation (CYP26) of RA, and by producing growth factors that support RA-driven differentiation (BMP4).

article, here we will primarily explore how somatic cells residing outside the SSC niche influence the dynamics of the undifferentiated pool; including macrophages, PMCs, Leydig cells and vascular cells.

Macrophages are primarily considered to be a phagocytic cell involved in immune defense, however it is becoming apparent that these cells play an alternate role in the testis. Indeed, two populations of testicular macrophages exist, one within the interstitium and the other directly on the surface of the seminiferous tubules (DeFalco et al., 2015). These testicular macrophages are biased toward an M2 phenotype, meaning that they have far less pro-inflammatory properties than bone macrophages, and instead may have an immunosuppressive function (Wang et al., 2017). In assessing macrophage interaction with the spermatogonial population, recent observations by DeFalco et al. (2015) noted that, although not in direct contact with peritubular macrophages, the undifferentiated spermatogonial pool appears to preferentially reside adjacent to these cells. To confirm crosstalk and a direct functional link between macrophages and spermatogonia, targeted ablation of the testicular macrophage population was instigated. Remarkably, following macrophage ablation, 75% of the undifferentiated spermatogonial population (as labeled by ZBTB16 immunostaining) was lost. While the full extent of the macrophage-spermatogonia interaction remains unknown, DeFalco et al. (2015) did identify expression of the growth factor Colony Stimulating Factor 1 (CSF1) by the peritubular macrophage population. Importantly, it has been demonstrated that CSF1 can work alongside GDNF and FGF2 to directly influence SSC maintenance and self-renewal; with CSF1 supplementation to primary cultures of spermatogonia stimulating a threefold enrichment in SSC content over 63 days; as demonstrated by spermatogonial transplantation analyses (Oatley et al., 2009). Indeed, expression of the CSF1 receptor (CSF1R) is significantly upregulated in populations of spermatogonia that are enriched for SSC content using THY1 + selection (Oatley et al., 2009); further suggesting that this growth factor is important for regulating SSC activities in the testes, and that peritubular macrophages may play a role in stimulating self-renewal in the SSC pool (Fig. 1).

The potential origins of CSF1 span beyond the testicular macrophage population, with immunostaining analyses showing that a portion of the PMC population also express this growth factor (Oatley et al., 2009) (Fig. 1). The PMCs are a flattened muscle-like cell that surround the outer of the basal lamina of the seminiferous tubule, and are thought to aid progressive transport of male germ cells through the seminiferous tubule via their contractile activity (Maekawa et al., 1996). In addition to production of CSF1, their ability to potentially influence the spermatogonial population spans to the production of another growth factor; leukemia inhibitory factor (LIF) (Piquet-Pellorce et al., 2000). LIF production in the rodent testis was identified using an RT-PCR approach, and was sourced primarily to the PMC population following purification of each testicular somatic cell type (Piquet-Pellorce et al., 2000). Some evidence exists to suggest that LIF, like CSF1, works alongside GDNF to stimulate SSC proliferation. This evidence comes from in vitro studies in which LIF has been supplemented into rodent spermatogonial cultures both alone (Kubota et al., 2004; Wang et al., 2014), and in conjunction with GDNF (Wang et al., 2014). While both independent research groups reported no significant improvement in SSC content (Kubota et al., 2004) nor proliferation of cultures (Wang et al., 2014) following the additional of LIF alone, Wang et al. reported that a combination of LIF and GDNF significantly improved proliferation in these cultures (Wang et al., 2014). Despite this, the spermatogonial population observed by Wang et al. was heterogeneous; being comprised of both SSCs and progenitors, thus the significance of LIF production by PMCs in the testes in terms of spermatogonial regulation remains undetermined.

In addition to the production of CSF1 and LIF, investigation has also been conducted into PMCs as an alternate source of GDNF itself, contributing to the stimulation of maintenance and self-renewal of the SSC population (Spinnler et al., 2010; Chen et al., 2016) (Fig. 1). In the human testis, PMCs have been shown to express GDNF using immunocytochemistry techniques, and isolated PMCs were demonstrated to release GDNF into surrounding culture media (Spinnler et al., 2010). Further, in the mouse, it has been reported that conditional knockout of GDNF in PMCs results in diminishment of the undifferentiated spermatogonial population, and as a consequence, an age-associated decline in fertility (Chen et al., 2016). Despite this, an independent research group (Chen and Liu, 2016) have pointed out that the Myh-11 Cre utilized by Chen et al. (2016) is not specific for the PMC population, but rather its expression transcends all types of smooth muscle cells (Xin et al., 2002). Thus, although expression of GDNF by PMCs in the testis is evident, further investigation into the relevance of this in regulating activities of the undifferentiated spermatogonial pool is required. As a whole, however, it is apparent that the PMC population has the capacity to synthesize and secrete a number of growth factors that are known to be influential on the undifferentiated spermatogonial pool.

The Leydig cells exist in the interstitial space where their primary function is to synthesize androgens in response to stimulation by luteinizing hormone. Although the Leydig cells are not likely to directly influence the spermatogonia in this manner as spermatogonia do not express the androgen receptor (Sar et al., 1990), it has been demonstrated that androgens can indirectly influence activities in the spermatogonial pool. Specifically, Leydig cells stimulate the production of FGF2 by Sertoli cells (Gonzalez-Herrera et al., 2006); which, as mentioned previously, is critical for working alongside GDNF to stimulate maintenance and self-renewal of the SSC pool (Kubota et al., 2004). Additionally, androgen secretion has been proposed to stimulate GDNF production by PMCs (Chen et al., 2014, 2016). In conjunction with their primary role in androgen synthesis, Leydig cells also secrete a number of factors themselves that are known to influence proliferation of the spermatogonial population; thus, these cells may also have a direct influence on the spermatogonial population. Such factors include Insulin like growth factor 1 (IGF1); which has been shown to significantly improve proliferation of SSCs in cultures of undifferentiated spermatogonia (Kubota et al., 2004), as well as CSF1 (Oatley et al., 2009). Again, these findings suggest that the Leydig cells may play some role in maintaining the undifferentiated spermatogonial pool in the testis.

While this review has thus far considered how growth factors produced by somatic cells can influence the undifferentiated spermatogonia population; when discussing the vascular cells in the testes we also need to consider the influence of oxygen tension.

While other *closed* stem cell niche systems such as the hematopoietic niche are for the most part accepted to maintain hypoxic conditions (reviewed by Eliasson and Jönsson, 2010), it is controversial as to whether this is the case in the germline stem cell niche. A study by Yoshida et al. (2007) reported that “SSCs” preferentially exist in regions of the seminiferous tubule adjacent to vasculature. However, the SSC marker used in this study was Nuerogenin3 (NEUROG3), which has more recently been described to preferentially label the transit amplifying progenitor population (Nakagawa et al., 2010; Kaucher et al., 2012; Hara et al., 2014). Contrastingly, a study by our own research group suggested that SSCs preferentially reside in avascular regions of the testes (Chan et al., 2014), in this case utilizing ID4 as an SSC marker; a transcription factor whose expression has been shown to be highly enriched in the SSC population, and that can be used to isolate a seemingly pure population of SSCs (Chan et al., 2014; Helsel et al., 2017b). In considering the influence of oxygen tension, and thus association with vascular cells, on the spermatogonial population; the beneficial nature of hypoxic conditions on maintenance of the SSC pool has recently been demonstrated using in vitro culture studies (Helsel et al., 2017a). Indeed, when maintained in atmosphere of 21% oxygen and 5% CO₂, SSCs in primary culture have a significantly diminished life span of regenerative capacity when compared to their counterparts cultured in 10% oxygen and 5% CO₂ (Helsel et al., 2017a). Interestingly, in addition to regulation of oxygen tension, the possibility that vascular cells also interact with the undifferentiated population via production of growth factors cannot be discounted. Indeed, DeFalco et al. (2015) have suggested that CSF1 could be released from the perivascular compartment, while Chen and Liu (2016) have suggested, based on immunofluorescence staining, that some GDNF production may occur within the vasculature (Chen et al., 2016). Clearly, the functional relevance of growth factor production within the vascular compartment in terms of regulation of the spermatogonia pool requires further investigation, however, the potential impact of proximity of spermatogonia to the oxygen carrying erythrocytes within these structures has certainly been shown to have the capacity to influence SSC maintenance and functional longevity.

Clearly, the ability for somatic cells to interact with and influence self-renewal of SSCs and maintenance of the undifferentiated pool is highly intricate and spans beyond the direct Sertoli-spermatogonia association that occurs within the niche. However, the signals that stimulate maintenance of the undifferentiated pool must be balanced by signals that drive differentiation of the transit amplifying progenitors; lest the production of mature spermatozoa be halted. In the next section, somatic cell production and degradation of RA; the spermatogonial differentiation-driving signal, will be explored.

Involvement of Somatic Cells in Driving the A to A1 Transition in Spermatogonia

The critical role for the vitamin A metabolite RA in continuation of spermatogenesis has been appreciated since the 1920's (Wolbach and Howe, 1925). More recently, vitamin A- and RA- deficient rodent models have been characterized; depicting a complete block in spermatogenesis at the stage of spermatogonial differentiation that can be rescued by exogenous RA treatment (van Pelt and de Rooij, 1990, 1991; Hogarth et al., 2013). Exogenous RA drives differentiation in transit-amplifying progenitors via interaction with the RA receptors, “RARs” and their heterodimerization partners, the retinoid X receptors (RXRs). Upon the appearance of RA, RAR/RXR heterodimers bind to RA responsive elements (RAREs) in specific genes, modulating their expression (reviewed by Cunningham and Duester, 2015). Two classically upregulated genes that are indicative of the RA-driven differentiating transition in spermatogonia are *Kit* and *Stimulated by retinoic acid 8 (Stra8)* (Pellegrini et al., 2008). As with VA deficient models, knockdown of *KIT* results in cessation of spermatogenesis as a consequence of a block in the differentiating transition (reviewed by Rossi et al., 2000). Contrastingly, knockdown of *STRA8* expression instigates a less severe phenotype, however a disruption of spermatogonial differentiation is still apparent (Endo et al., 2015).

Clearly, it would not be beneficial for RA to be constantly present in the spermatogonial microenvironment, as this could result in exhaustion of the undifferentiated pool. Instead, the seminiferous cycle is such that a pulse of RA occurs in a “wave” along the length of the tubule every 8.6 days, is rapidly degraded, and is bookended by conditions that stimulate rebuilding of the transit-amplifying progenitor population (Hogarth et al., 2015a). The synthesis of RA at stages VI–VIII of the seminiferous cycle (Hogarth et al., 2015a), and the subsequent degradation, is thought to be controlled in part by somatic cells in the testis. The Sertoli cells in particular have been thoroughly investigated, and play an integral role in driving the differentiating transition in spermatogonia via their capacity for RA synthesis and storage (Tong et al., 2013), as well as production of enzymes for RA degradation (Hogarth et al., 2015b).

Sertoli cells possess isoforms of both retinol dehydrogenase (RDH) and aldehyde dehydrogenase (ALDH) enzymes that act to convert dietary Vitamin A into its metabolite retinal, and subsequently convert retinal into biologically active RA, respectively (Tong et al., 2013; Kent et al., 2015). The requirement for these Sertoli expressed enzymes for the A to A1 transition in spermatogonia is highlighted by a series of conditional knockout and inhibitor studies in rodent models. For instance, knockout of *Rdh10* in Sertoli cells results in a significant reduction in the percentage of *KIT* and *STRA8* positive spermatogonia in neonatal mice, while simultaneous loss of *RDH10* expression in Sertoli and germ cells results in a complete block in spermatogonial differentiation (Tong et al., 2013). Similarly, inhibition of ALDH activity using the compound WIN 18,446 mimics the phenotype of a vitamin A deficient mouse during neonatal life (Hogarth et al., 2013), with *ALDH1A1*, *ALDH1A2*, *ALDH1A3* and *ALDH8A1* isoforms being expressed in both somatic (Sertoli and interstitial) and germ cell populations of the testes; their specific localization depending on stage of development (Kent et al., 2015). In combining these data, one can conclude that the somatic cells, particularly the Sertoli cells, undoubtedly play a role in synthesizing RA to drive spermatogonial differentiation during the first wave of spermatogenesis in neonatal life. However, these dynamics shift upon transition into adulthood, at which time RA synthesizing enzymes within later stage germ cells take on a role, and the degree to which Sertoli cells participate in RA synthesis in steady state conditions becomes

uncertain. Indeed, in *Rdh10* conditional knockout mice (Sertoli- and germ cell- specific), fertility is restored at ~10 weeks of age, suggesting that a new source of RA synthesizing enzymes appears at this time (Tong et al., 2013). Similarly, the capacity for ALDH inhibition to enforce a complete block of spermatogenesis is lost in the adult around the time that the first preleptotene spermatocytes appear (Raverdeau et al., 2012).

Importantly, although RA synthesis to drive differentiation of spermatogonia is primarily thought to be coordinated through Sertoli cells and later stage germ cells, it is also possible that other somatic cells in the testes are involved in regulating local RA levels. For instance, DeFalco et al. (2015) identified expression of the RA synthesis enzyme RDH10 in testicular macrophages, and showed that the differentiating population of spermatogonia was dramatically affected when the peritubular macrophage population was ablated. As such, it will be interesting to assess in the future how much of a contribution the macrophage population plays to RA synthesis in the testes.

In conjunction with somatic cell regulation of the differentiating transition in spermatogonia via the synthesis of RA, it is becoming apparent that regulation of this transition is also reliant on rapid degradation of the RA signal by CYP26 enzymes synthesized in the same somatic cell populations. Indeed, when *Cyp26a1* and *Cyp26b1* isoforms were simultaneously knocked down in Sertoli cell populations, precocious and overabundant expression of STRA8 could be identified in the spermatogonial population (Hogarth et al., 2015b), suggesting that rapid degradation of RA may be important to “hold back” a portion of the transit-amplifying progenitor pool from entering the differentiating pathway. Further, when *Cyp26b1* was knocked down in Sertoli and germ cells simultaneously, fertility was significantly impaired, and 96% of seminiferous tubules were found to be completely devoid of germ cells (Hogarth et al., 2015b). CYP26 expression is also evident in PMCs, where it has been postulated to act as a protective barrier for the spermatogonia from circulating retinoids that could stimulate unwanted transition into a differentiating state and loss of the undifferentiated pool (Vernet et al., 2006; Hogarth, 2015).

Finally, the differentiation-driving activities of the somatic cell population in the testis are not limited to RA synthesis and degradation, but also the synthesis of growth factors that act alongside RA to stimulate the A to A1 transition. Specifically, bone morphogenic protein 4 (BMP4) has been shown by northern blot analysis to be synthesized by Sertoli cells in early postnatal life (Pellegrini et al., 2003). Experimental evidence suggests that BMP4 works alongside RA to stimulate differentiation in spermatogonia, as well as DNA synthesis, and the expression of key differentiating markers such as KIT and STRA8 (Pellegrini et al., 2003; Yang et al., 2016). As BMP4 expression begins to decline in Sertoli cells from post-natal day 7, this somatic cell signal is primarily thought to be influential on the spermatogonial population in postnatal life (Pellegrini et al., 2003).

Conclusions

Somatic cell interactions drive a number of different spermatogonial responses in the mammalian testes, depending on the stage of the cycle of the seminiferous epithelium, as well as the subset of the spermatogonial population being examined. In this review, we have detailed how testicular somatic cells, even those that reside on the outer of the seminiferous tubules—thus not in direct contact with spermatogonia, produce a number of growth factors that can stimulate self-renewal of SSCs as well as maintenance of the undifferentiated spermatogonial pool. These growth factors include GDNF produced by Sertoli cells and PMCs; FGF2 produced by Sertoli cells, and CSF1 produced by macrophages, PMCs and potentially Leydig cells. Further, this review has explored how somatic cells; particularly the Sertoli cells, also orchestrate transition to a differentiating state in a subset of transit amplifying progenitors at stages VI to VIII of the seminiferous epithelial cycle by regulating synthesis and degradation of RA. In conclusion, the somatic cells in the testes play an indispensable role in regulating cell fate decisions of spermatogonia, ensuring that the self-renewing SSC reservoir is not lost, and driving spermatogonia through a differentiating pathway at discriminant times to maintain continual sperm production throughout the life of the adult male.

Differential Expression of Golgi Proteins During Spermatogenesis

Louis Hermo, Regiana L Oliveira, Charles E Smith, and John JM Bergeron, McGill University, Montreal, QC, Canada

Introduction

The Golgi apparatus is a cellular organelle that is found in each of the estimated greater than 200 different cell types that make up the human body (Valentine et al., 1994). The Golgi apparatus plays a major role in protein biosynthesis, post-translational modification of endoplasmic reticulum (ER) derived proteins and as a sorting station for proteins directed for the plasma membrane, lysosomes and other destinations. Golgi apparatus structure visualized by standard thin sectioning techniques at the electron microscope (EM) level, that reached its apogee in the latter part of the last century, can identify solely and unambiguously any of the differentiated cell types in a given species (Clermont et al., 1995; Rambourg and Clermont, 1990). Remarkably, its structure is strictly conserved with the number and size of cisternae in Golgi stacks and overall size of the Golgi apparatus under strict control for each of the many differentiated cell types of a given tissue or organ of the human body. This conjecture is illustrated in this work for the Golgi apparatus of male germ cells in the adult rat testis as they undergo differentiation through the process called spermatogenesis.

Part 1: Spermatogenesis: A Discovery Based on the Golgi Apparatus

In order to fully understand the differential distribution of Golgi proteins during germ cell development, one must commence with an understanding of the organization and composition of the germ cell types comprising the many seminiferous tubules of the adult testis (Clermont, 1972). In mammalian species (our focus will be on the rat), these tubules are lined by a unique stratified seminiferous epithelium bordering a centrally located lumen (Fig. 1A–F). The seminiferous epithelium consists of germ cells that are at different phases of their differentiation process, with the end result being the production of sperm (Fig. 1A–F). The latter after being fully formed enter the centrally located lumen, whereby they then gain access to the epididymis, the site of sperm maturation. Germ cells are accompanied by nondividing Sertoli cells, which serve to support and nourish germ cells, but are beyond the topic of the present study (Fig. 1A–F).

On the other hand, germ cells in the seminiferous epithelium of the testis undergo a differentiation process as they evolve from the youngest germ cells called spermatogonia into maturing spermatozoa (Fig. 2). Defined as spermatogenesis, this event occurs over a span of several weeks and is characterized by a period of mitotic, meiotic and postmeiotic events (Fig. 2; Leblond and Clermont, 1952; Clermont, 1972; Steinberger and Steinberger, 1975; Clermont et al., 1993; Hermo et al., 2010a). Spermatogonia undergo several mitotic divisions to self-renew as well as gradually increase their numbers to eventually form spermatocytes. The latter undergo two meiotic divisions thereby reducing the number of chromosomes by half to form haploid spermatids, which subsequently undergo a structural metamorphosis to become spermatozoa (Fig. 2; Dym and Clermont, 1970). Spermatids undergo a series of dramatic structural and functional modifications and, as defined by acrosome development and sperm head shape alterations, result in 19 well defined steps in their differentiation, a process referred to as spermiogenesis, a subdivision of spermatogenesis (Fig. 3; Clermont, 1972; Hermo et al., 2010a; Hess et al., 2015).

A continuously renewing seminiferous epithelium creates a unique situation for the differentiation of germ cells unlike any other in the human body. In any given cross sectional profile of a seminiferous tubule, the different germ cell types develop in groups and form several concentric layers around the tubule. Generally, spermatogonia and early spermatocytes localize to the base of the epithelium, more advanced spermatocytes and early round spermatids occupy the mid region, and late elongating spermatids prior to release appear closest to the lumen (Fig. 1A–F). A distinguishing feature of the seminiferous epithelium is that the composition of germ cells in any given portion or segment along the length of the tubule can be very different from adjacent segments. In fact, only one of 14 unique germ cell associations, defined as stages, occupies a given cross sectional profile of a seminiferous tubule at any given time in the rat testis (Fig. 1A–F).

The key to figuring out the complexity of these cellular associations came with the discovery of the periodic acid Schiff (PAS) technique. In the mid-1950s, detailed light microscope observations elucidated the complexity of the differentiation pathway of male germ cells in the seminiferous epithelium of the testis. The PAS technique, specific to vicinyl hydroxyls and when applied to the testis, revealed staining of the Golgi apparatus and a Golgi derived membrane derived lysosomal structure called the acrosome that was being produced in a specific population of germ cells referred to as early spermatids (Figs. 2 and 3). The reaction due to carbohydrate modifications on glycoproteins was modulated by Golgi-localized glycosyltransferases. In fact it was the Golgi apparatus of spermatids and its role in the formation of the lysosomal acrosome, to be used by sperm at the time of fertilization of the egg that was the defining point in unraveling spermatogenesis. The developing acrosome which grew with time in size while attaching itself to the nucleus of spermatids, along with changes to the shape of the spermatid head (from spherical to elongating) served to identify 14 specific cellular associations that were called stages of the seminiferous epithelium. Examples of several stages can be seen in Fig. 1A–F. The PAS method provided a precise mapping of how germ cells associate with each other in the numerous cross sectional profiles of seminiferous tubules that made up the testis proper (Fig. 2) and has survived the test of time for future

Fig. 1 Cross sectional profiles of seminiferous tubules at different stages of the cycle are shown to enhance understanding of spermatogenesis as discussed in Part 1. Each tubule contains germ cells that are specific to the stage that they occupy as defined by the criteria set down by [Leblond and Clermont \(1952\)](#). The non-dividing Sertoli cells are also shown. Germ cells at one specific stage do not appear in another stage, establishing the precise order of spermatogenesis. These images also serve to localize proteins that were reactive for the Golgi apparatus at the stages indicated in each figure (A–F) as discussed in Part 2. LM-IF (A) of a tubule at stage III–IV and LM-IHC (B) of a tubule at stage VII revealing punctate reactions for the Golgi apparatus of germ cells and Sertoli cells of sections stained for TM9SF3. LM-IHC (C) of a tubular section at stage VIII showing reactive Golgi apparatus of germ and Sertoli cells stained for TMED7/p27. Rbs and the forming Hermes body are also reactive. LM-IHC (D) of a tubular section at stage V–VI revealing reactions over the Golgi apparatus of pachytene spermatocytes and steps 5–6 spermatids and the acrosome stained for GBF1. LM-IHC (E) of a tubular section at stage XIV showing Golgi reactions for germ cells stained for GL54D. LM-IHC (F) of a tubular section at stage V–VI revealing reactions over the Golgi apparatus of steps 5–6 spermatids and the acrosome stained for GPP34 (GOLPH3). Abbreviations: Lumen (Lu), pachytene (P) spermatocytes, cytoplasm of late spermatids (*asterisks*), Sertoli cells (S), seminiferous epithelium (SE), residual bodies (Rb), Golgi apparatus early (*small arrowheads*) and late (*large arrowheads*) spermatids, forming Hermes body (*curved arrows*), acrosome (A).

Setting the Stage for Germ Cell Differentiation and Golgi Protein Expression Profile

Cycling Through the Stages of Germ Cell Development

In addition **Fig. 2** shows how any given germ cell type will appear with time as it differentiates through the 14 stages of the cycle. In some cases these changes are simply a change in size (e.g. pachytene spermatocytes), or more dramatically shape (round nucleus of early spermatids versus elongating nucleus of late spermatids) or addition of newly formed structures (acrosome of early spermatids; tails of spermatids). Therefore, each generation of germ cells depicted in a given column of **Fig. 2** and representing a particular stage e.g. stage I, will advance in its development to form the distinct composition of generation of germ cells of the next stage, i.e. stage II. This continues for germ cells at stage II to stage III and so forth and so on until stage XIV, whereupon

Fig. 3 Schematic representation of the role of the Golgi apparatus in acrosome formation during spermiogenesis as visualized by the PAS method. At step 2 the Golgi apparatus seen as a small *magenta colored bubble* has formed two small dense proacrosomic granules placed next to the nucleus, which at step 3 have fused together to form a single larger dense granule. At step 6 the acrosome has grown in size and covers a sizeable portion of the nucleus. At step 8 the nucleus occupies an eccentric position next to one pole of the nucleus, while the Golgi apparatus becomes spherical in shape and floats freely in the cytoplasm. From steps 10–19 the nucleus becomes gradually compacted, elongated and sickle shaped. The spherical Golgi apparatus is still evident as a *reddish bubble* in the vast cytoplasm of these cells. At step 19a, the cytoplasm has displaced itself along the tail to form the residual body (RB) seen hanging as a sac onto the sperm at the junction of its head and tail. At step 19b, the residual body has completely liberated itself from the sperm, while a small dilated focal area of cytoplasm at the neck region of the tail constitutes the Hermes body (HB) (cytoplasmic droplet). It reveals the presence of a small reddish remnant of the Golgi apparatus, as does the residual body. Reproduced with permission from Wiley: *Andrology*, 2015 Nov; 3 (6):1015–21. Hess RA, Hermo L, Robaire B; Lessons learned in andrology: Yves Clermont, an interview by Lonnie D. Russell.

germ cells of stage I then reappear. The sequential appearance of the different generation of germ cells from stage I to stage XIV and then back to stage I constitutes the so-called cycle of the seminiferous epithelium.

Here is how this works. An important feature of germ cell differentiation is that the different generations of germ cells at a given stage are evolving over time in a given segment of a tubule that they occupy, i.e. germ cells do not move laterally along the tubule as they differentiate. Indeed, if one were able to watch in the living organism the various generations of germ cells defining a distinct stage, e.g. stage I, at a particular segment of the tubule, with time the different germ cell generations would evolve into those characterizing the next stage (stage II), and this would go on and on until stage I would reappear once again in that same segment of the tubule. Hence germ cells advance in differentiation in a given cross sectional profile of the tubule that results in all 14 stages appearing in a particular area of the tubule over time. Leblond and Clermont (1952) defined the advancement of germ cell differentiation over the 14 stages of a given area of the tubule as the “cycle” of the seminiferous epithelium (Fig. 2). Considering that sperm are being released continuously at the end of spermatogenesis, the different generations of germ cells evolve and advance in development, and this continuous production is due to the actively mitotic divisions of the spermatogonial stem cells.

Using a variety of techniques, the duration of each stage of the cycle of the seminiferous epithelium was calculated and shown to be constant but varying in time for different stages (Fig. 2). Some stages lasted for a short period of time, while others lasted longer, i.e. stages IX and X, 7 h; stage VII, 58 h. Adding up the different durations of each stage, the total duration of the cycle was calculated to be 12.9 days in Sprague Dawley rats and that of the complete process of spermatogenesis 51.6 days (Clermont and Harvey, 1965; Clermont, 1972). A comprehensive analysis of the stages of the cycle of the rat and several other species is provided in a complete book on the testis (Russell et al., 1990). A video by W. Vogl and R. Hess depicting the 14 stages of the cycle of the rats in time can be viewed at <https://www.facebook.com/stagescycle/>. In addition, for those that might be interested, the gross characteristics of adult rat seminiferous tubules, first described by Clermont and Huckins (1961), has been elegantly redefined in a 3D reconstruction of their number, length, run and mutual relationships (Nakata et al., 2015, 2017). Knowledge of the stages of spermatogenesis is also useful for analyzing abnormalities in mutant mice undergoing different degrees of germ cell generation (Meistrich and Hess, 2013). An assessment of the functions of several critical genes during spermatogenesis has been examined in mutant mice (Matzuk and Lamb, 2008; Lin and Matzuk, 2014).

Spermiogenesis: A Key Event for Golgi Apparatus Function Serving Sperm Fertilizing Capability

Spermiogenesis is a timely event defining the last phase of germ cell differentiation. It begins after the 2nd meiotic division of spermatocytes with the formation of haploid spermatids and follows them through their metamorphosis into spermatozoa. It is subdivided into distinct steps with 19 being identified in rats; the entire process extends over 22.7 days (Fig. 3). During spermiogenesis, many genes/proteins are expressed, some for the first time, with implications in the diverse dynamic events occurring at this time point of germ cell development. These events include formation of the flagellum, nuclear condensation, and modification of specific organelles, such as the Golgi apparatus and ER. A significant event is formation of the acrosome by the Golgi apparatus of early spermatids leading to the formation of spermatozoa enhanced with the ability to penetrate the protein coats of the egg (Clermont et al., 1993; Hermo et al., 2010a,b; Gao et al., 2016).

The Good, the Bad and the Sticky

The Golgi apparatus (the good) of early spermatids is the key player in the formation of the acrosome during the early steps of spermiogenesis. The acrosome (the bad) is a membrane bound lysosome filled with an arsenal of hydrolytic enzymes that is used at the time of fertilization to break through the coverings of the egg. The nucleus (sticky) provides a platform for tight binding of the acrosome to ensure its presence on the sperm at the time of fertilization. Hence the Golgi apparatus, acrosome and its attachment to the nucleus are critical to fertilization.

The Golgi Apparatus Forms the Acrosome During Steps 1–7 of Spermiogenesis

Steps of spermatid differentiation, as defined by Golgi identification and acrosome formation were discovered through the PAS reaction which alone enabled a distinction in the rat amongst the transformation of early round spermatids (steps 1–8) to late elongated spermatids (steps 9–19) (Leblond and Clermont, 1952; Hermo et al., 2010a). The PAS staining of the Golgi apparatus and the acrosome is found in the original illustration from Dr. Yves Clermont shown here in Fig. 3.

From steps 1–3 spermatids as noted in the LM, small proacrosomic granules made by the hemispherical Golgi apparatus appear adjacent to the spherical nucleus. With continued production these granules fuse with one another creating a larger membrane bound structure called the acrosome (step 4). The latter applies itself to the nuclear surface to which it tightly adheres, and with time and progressive enlargement by contributions from the Golgi apparatus, it spans more and more of the nuclear surface (steps 5 and 6), until its formation is completed at which time it covers almost half of the nuclear circumference (step 7) (Fig. 3). During acrosome formation, the hemispherical Golgi is closely associated with the developing acrosome at one pole of the nucleus.

Stacking of Golgi Cisternae and Tubular Interconnections to Form the Golgi Ribbon: The Dynamics of the Golgi Ribbon in Forming the Acrosome

The structure of the Golgi apparatus of early spermatids at the time of acrosome formation has been described amply by EM analysis (Thorne-Tjomsland et al., 1988; Griffiths et al., 1981; Hermo et al., 2010a,b; Hermo et al., 1980; Susi et al., 1971; Hermo et al., 2018). The Golgi apparatus is a continuous structure with alternating compact stacked and non-compact tubular interconnecting regions (Hermo et al., 1980; Clermont et al., 1994; Thorne-Tjomsland et al., 1988; Fig. 4), with an overall appearance in mammalian cells to that of a ribbon. The term Golgi ribbon was first introduced by Rambourg and Clermont (1990). Its usage has been adopted universally by the scientific community to define the conserved properties of Golgi apparatus structure in all mammalian cell types (Jarvela and Linstedt, 2014; Vinke et al., 2011; Lavieu et al., 2014).

In essence, the stacked compact region of the Golgi ribbon consists of a highly organized assembly of tightly apposed flattened cisternae (Fig. 4). The latter show remarkable structural differences from the *cis* (forming) face to the *trans* (mature) face of the Golgi stack. Proteins synthesized in ER cisternae facing the *cis* face and carried by vesicles fuse with an anastomotic closely knit tubular network (CGN) forming the *cis*-most element of the Golgi ribbon. Beneath and closely opposed to one another are nine flattened cisternae. Dilated tubules extend from the edges of these flattened cisternae and serve to connect adjacent compact regions to each

Fig. 4 Schematic representation of the Golgi apparatus of a step 7 spermatid. Represented are stacks of Golgi cisternae (S) forming the compact zone and dilated tubules extending from the cisternal edges serving to join adjacent stacks that form the non-compact zone (NCZ). The Golgi stack consists of an anastomotic tubular network on the *cis* face called the CIS-Element, mid cisternae stained for NADPase, a *trans* cisterna stained for TPPase and 2 CMPase cisternae called the trans Golgi networks. The latter reveal bristle (clathrin) coated buds at their edges and a peeling off configuration. Endoplasmic reticulum (ER) is seen overlying the *cis* element, applied to *trans* cisterna and the TGN, as well as in the NCZ and core or medulla (M) of the Golgi apparatus. Pan shaped spaces of the *cis* cisternae form wells (W). Vesicular aggregates (VA) also appear on the *cis* face of the Golgi apparatus. This material was originally published in Cell and Molecular Biology of the Testis, chapter 14 "Cell Biology of Mammalian Spermatogenesis", Clermont, Y., L. Hermo, and R. Oko. 1993, edited by Claude Desjardins and Larry L. Ewing and has been reproduced by permission of Oxford University Press.

other. These tubules form the so-called non compact regions. Overall the various Golgi stacks and interconnecting non compact regions form a continuum defining the Golgi ribbon. Many small 50–60 nm vesicles and tubules are associated with the Golgi ribbon (Fig. 4).

On the trans-most side of the Golgi ribbon, 1–3 morphologically distinct thickened cisternae characterize the so-called trans Golgi networks (TGNs), which at times reveal a peeling off configuration from the Golgi ribbon (Fig. 4). Vesicular budding showing a bristle or clathrin coat is often seen emanating from their edges. The TGNs are apposed to the developing acrosome, which during its formation applies itself to one pole of the nuclear surface. Continuity between the TGN and acrosome are seen but rarely. The area in between the TGNs and the developing acrosome also contains many vesicular and tubular profiles decorated with bristle coats, some of which fuse with the acrosome (Burgos and Gutierrez, 1986; Mollenhauer and Zebrun, 1960; Susi et al., 1971). EM cytochemical markers indicate that nicotinamide adenine dinucleotide phosphatase (NADPase) localizes to middle cisternae, thiamine pyrophosphatase (TPPase) to the trans most cisternae, and cytidine 5-monophosphatase (CMPase) to the TGNs (Fig. 4; Clermont et al., 1981; Smith et al., 1990; Thorne-Tjomsland et al., 1988). Because the acrosome also shows a cytochemical reaction for CMPase, TPPase, it is suggested that these respective Golgi cisternal elements contribute directly to acrosome formation (Thorne-Tjomsland et al., 1988; Hermo et al., 2010b). As the TGNs reveal a peeling off configuration from the stack and an apparent breakdown of their structure into tubules and vesicles, it has been suggested that the Golgi cisternae turnover as they form the acrosome (Thorne-Tjomsland et al., 1988). But this theory may be an oversimplification of Golgi dynamics as will be discussed in Part 2.

Postacrosome Phase of Spermiogenesis (Steps 8–18): The Golgi Is Functional After Acrosome Formation

Beginning at step 8 and thereafter, the Golgi apparatus becomes spherical and migrates away from the acrosome to lie freely in the cytoplasmic lobe of late spermatids. At later steps of spermiogenesis, it continues to be involved in glycoprotein synthesis destined for the plasma membrane (Batista et al., 2012; Clermont and Tang, 1985; Susi et al., 1971; Clermont et al., 1993). During this time, the acrosome conforms to the changes to the shape of the nucleus, which in the rat takes on its species-specific sickle shaped appearance. At step 15 the Golgi ribbon begins to fragment and become vacuolated (Susi et al., 1971), with individual flattened cisternae of the compact Golgi stack dispersing into the cytoplasm (Oko et al., 1993).

Step 19 Spermatid (The Last Frontier): The Golgi Cisternae Congregate Into the Forming Hermes Body (Cytoplasmic Droplet)

At the last step of spermiogenesis, the flattened Golgi cisternae of the step 19 spermatids congregate into a small pouch of cytoplasm located at the neck region of the flagellum, formerly called the cytoplasmic droplet (Oko et al., 1993), and renamed recently as the

Hermes body (Au et al., 2015a). These authors have suggested a role for the Golgi cisternae and other proteins of the Hermes body in the maturation of sperm as they traverse the epididymal duct. This topic is discussed in a separate section of the Encyclopedia of Reproduction.

Part 2: Defining Golgi Proteins Expressed in Germ Cells During Spermatogenesis

One of the shortcomings about the Golgi ribbon of germ cells is the lack of appropriate markers across the full spectrum of germ cell differentiation. In 2015, a reproducible method to isolate Golgi apparatus selectively from male germ cells of whole adult rat testis homogenates was developed (Au et al., 2015a). By quantitative proteomics, a characterization of over 1000 different proteins in this subcellular fraction was elucidated, with several representing novel Golgi proteins as well as known Golgi proteins.

With monospecific antibodies to 20 different proteins obtained from different sources (Au et al., 2015a) and concluded to be Golgi localized by LM immunohistochemical localization (LM-IHC), a map of their expression profile during spermatogenesis was realized. Here we discuss 14 of these Golgi proteins to illustrate their complex distribution pattern during the process of germ cell differentiation (spermatogenesis) in attempting to define their functional significance to spermatogenesis. The insight gained from the detailed analysis of this data will be summarized by the illustration of spermatogenesis truncated to 30 of the 64 distinct cell types identified. Here germ cells are represented undergoing mitosis, meiosis, acrosome formation (steps 1–7), postacrosome Golgi migration (steps 8–18), and ending at the terminal step of spermiogenesis, step 19 spermatids (Fig. 5). A more detailed analysis of Golgi proteins in germ cells based on the work of Au et al. (2015a) and that of others can be found in Hermo et al. (2018).

Defining Golgi Proteins to Specific Germ Cells During Differentiation Using the Staging Scheme of Leblond and Clermont (1952)

Golgi proteins localized to spermatogonia, spermatocytes and spermatids: TMED7/p27, TMED4/p25 and TM9SF3

The periodic renewal of type A spermatogonia was recognized early in the last century (Regaud, 1901), but the complex process of spermatogonial renewal is only being fully understood 60 years later. In the early 1950s, it was the inspirational work of Clermont and Leblond (1953) that first defined stem cells in the testis and paved the way for all subsequent significant contributions on their renewal (Oatley and Brinster, 2008; Yoshida et al., 2009; Griswold, 2016; Mecklenburg and Hermann, 2016; Boitani et al., 2016; Komeya and Ogawa, 2015).

While there are many descriptions of markers for undifferentiated and differentiated spermatogonia (Herme et al., 2010a), those that demarcate the Golgi apparatus of these cells are lacking. Three of the 20 proteins characterized by Au et al. (2015a), although widely distributed throughout spermatogenesis, clearly labeled the Golgi apparatus of spermatogonia. These were one member of the transmembrane superfamily 9, TM9SF3, and two members of the TMEDp24 (transmembrane emp24 domain) family of Golgi (GOLD domain) integral membrane proteins, TMED4/p25 and TMED7/p27.

In the isolated germ cell Golgi fraction, three members of the TM9SF family of proteins of unknown function were identified (Au et al., 2015a). Localization of one of these, TM9SF3, revealed it to be a Golgi integral membrane protein uncovered for the first time as a Golgi marker not only to germ cells but also with a ubiquitous expression in other cell types, such as Sertoli and Leydig cells, epididymal epithelial cells (Au et al., 2015a) and neurons of the brain (unpublished data). In germ cells, TM9SF3 was expressed in the Golgi apparatus from spermatogonia to step 16 spermatids (Figs. 1A, B and 5). TM9SF3 has been shown to positively regulate cell proliferation and hence may play a role during the many mitotic divisions occurring during spermatogonial renewal of stem cells and more differentiated spermatogonia (Shen et al., 2017).

TMED4/p25 and TMED7/p27 proteins also revealed a widespread distribution commencing in spermatogonia and extending to late spermatids (Au et al., 2015a). However, while TMED4/p25 extended from spermatogonia to step 16 spermatids, TMED7/p27 was maintained in step 19 spermatids and in the forming Hermes body (Figs. 1C and 5). TMED2/p24 was also expressed in germ cells but only at step 19 spermatids (see below).

The TMEDp24 (transmembrane emp24 domain) family of Golgi (GOLD domain) membrane proteins regulate trafficking, cargo selection, and lipid makeup of Golgi derived carriers (Dominguez et al., 1998; Pastor-Cantizano et al., 2016). Ten TMED proteins are subdivided into four subfamilies based on sequence similarity (Strating and Martens, 2009). They are regulated during differentiation and development in many cell types (Jerome-Majewska et al., 2010) and may serve this function in germ cells.

Golgi protein localized exclusively to spermatocytes (MG160)

Meiosis is unique to germ cells and involves one round of DNA replication followed by two consecutive cell divisions enabling diploid cells to form haploid cells. Meiosis serves important cellular activities such as DNA repair, genetic exchange, and synapsis of homologous chromosomes, with many genes implicated in this process (Herme et al., 2010a; Mikolcevic et al., 2016; Griswold et al., 2012).

One of the 14 Golgi proteins analyzed by Au et al. (2015a) was expressed solely in spermatocytes. MG160 (Golgin160/MEA-2/Golga3) is a coiled coil protein and part of the Golgin family (Munro, 2011). It is normally expressed in all somatic cells and is a universal Golgi marker (Bell et al., 2001; Dahan et al., 1994). MG160 has long been known to be a prominent gene product of male germ cells (Kondo and Sutou, 1997). In the testis, MG160 expression demarcates the boundary between spermatogonial renewal and spermiogenesis, i.e. spermatocyte differentiation, with expression exclusive to spermatocytes (Au et al., 2015a; Fig. 5). When the gene is truncated in a transgenic mouse model, exactly as for the MG160 null mutant, spermatocytes are depleted

Fig. 5 Thirty representative germ cell types are depicted as they undergo differentiation during spermatogenesis. Illustrated are the mitotic spermatogonia types A, intermediate (In) and B; spermatocytes undergoing meiosis: preleptotene (PL), leptotene (L), zygotene (Z), pachytene (P), diplotene (Di) and secondary spermatocytes (II). Spermatids evolving through 19 steps of spermiogenesis that can be subdivided into acrosome formation (1–7), postacrosome events (8–18) and Hermes body (cytoplasmic droplet) formation (step 19). The expression profile of each Golgi protein in accordance with the different phases of germ cell differentiation is depicted by a specific colored line as deduced by analysis of germ cells at all 14 stages of the cycle from LM-IHC experimentation.

(Bentson et al., 2013). Sperm development is decreased and the resultant few sperm are infertile. MG160 has been implicated in tethering Golgi mini stacks together (Cheung and Pfeffer, 2016), and in this role it may be implicated in the doubling in size of the Golgi apparatus of spermatocytes and its eventual partitioning into four Golgi apparatuses with each one destined for the four resulting haploid spermatids (Suarez-Quian et al., 1991).

Golgi proteins localized to spermatocytes and spermatids (GBF1 and GL54D)

GBF1 is one of the guanine nucleotide exchange factors for ADP-ribosylation factor that regulates vesicular trafficking for active secretion by recycling between *cis*-Golgi and the ER (Wright et al., 2014). GBF1 expression begins at preleptotene spermatocytes

and continues through spermatocyte development with expression extending into early spermatids from steps 1–7 where it localizes to the Golgi apparatus and acrosome (Au et al., 2015a; Figs. 1D and 5). Hence the burst of GBF1 expression in spermatocytes and early spermatids likely reflects their high secretory activity. In fact, forerunners of the proacrosomic granules first appear in zygotene primary spermatocytes and extend into late pachytene spermatocytes (Anakwe and Gerton, 1990; Fawcett, 1975), with acrosome formation advancing through the first half of spermiogenesis (Hermo et al., 2010a,b) when GBF1 is also expressed (Au et al., 2015a).

A study of the isolated testis germ cell Golgi fraction (Au et al., 2015a) revealed that the most abundant Golgi protein was a protein designated from the annotation of UniProtKB/Swiss-Prot, as GLYCOSYLTRANSFERASE 54 DOMAIN-CONTAINING PROTEIN (GL54D), an MGAT4 family member also known as GnT1IP-S (Huang and Stanley, 2010). GL54D was uncovered for the first time at the endogenous protein level by mass spectrometry of the isolated testis Golgi fraction by Au et al. (2015a). GL54D, a type II, N-linked integral membrane terminally glycosylated glycoprotein largely facing the lumina of Golgi cisternae is a Golgi marker like TM9SF3. However, whereas TM9SF3 is ubiquitous to many cells as a universal Golgi marker, GL54D is germ cell-specific revealing a differential expression profile during spermatogenesis. GL54D is first detected in pachytene spermatocytes at stage VII of the cycle with expression extending up to step 16 spermatids (Figs. 1E and 5). Its initial onset of expression coincided exactly with that of the glucose transporter 3 (GLUT-3) protein that decorates the plasma membrane of germ cells and where it may be involved in its transportation to the cell surface (Au et al., 2015a). GLUT-3 was also noted to be the most abundant protein of an isolated Hermes body fraction of sperm, where it was proposed to serve as an ATP energy source for initiation of sperm motility as sperm transited through the epididymal duct (Au et al., 2015b).

Golgi proteins localized to early spermatids for acrosome formation (steps 1–7)

In addition to TMED7/p27, TMED4/p25, TM9SF3, GL54D, and GBF1 all with varied distributions, several additional proteins with Golgi characteristics (GRASP55, GPP34, Man2 α 1, ManIIX and LAMAN) revealed onset of Golgi expression in early spermatids during acrosome formation (Au et al., 2015a).

The acrosome is a lysosomal structure that is formed by the Golgi apparatus during early spermiogenesis (steps 1–7), with an unprecedented specificity for adherence to the nuclear surface of spermatids (Fig. 3). As such it follows the contours and modifications that occur to the shape of the head and nucleus of spermatids during late steps of spermiogenesis (Hermo et al., 2010b). At the time of fertilization, sperm undergo the acrosome reaction, an event unique in the life of a spermatozoon. Acrosomal contents released during fertilization promote sperm penetration through the oocyte's investments, leading to sperm-egg interaction and fusion (Hermo et al., 2010c). Acrosome formation is an intense period of protein synthesis that is marked by the expression of a plethora of proteins localized to the Golgi and developing acrosome (Hermo et al., 2018). In this article, we present only a few of the many Golgi proteins involved in acrosome formation. However, the list of Golgi proteins critical for acrosome formation is impressive and continues to grow as evidenced from numerous studies involving mutant and/or deficient mouse models (see reviews Foster and Gerton, 2016; Niu et al., 2016; Hermo et al., 2018).

GRASP 55 and GPP34

GRASP55 (Golgi reassembly protein) has been implicated in the stacking of Golgi cisternae (Bekier et al., 2017; Zhang and Wang, 2015; Seemann et al., 2000; Shorter et al., 1999). In the testis, its expression first appears after meiosis with Golgi immunoreactivity limited to steps 1–7 spermatids (Au et al., 2015a; Fig. 5) with involvement in acrosome formation, along with interactions with junctional adhesion molecule-C (Cartier-Michaud et al., 2017). However, no localization was noted for the Golgi apparatus of Sertoli or Leydig cells of the testis, all of which reveal stacked Golgi cisternae (Rambourg et al., 1974; Christensen, 1975). Alternative functions to those of cisternae stacking have been proposed for GRASP55 such as unconventional protein secretion and Golgi ribbon formation (Rabouille and Linstedt, 2016). Unlike typical lysosomes, the acrosome has to bind to the nuclear surface of spermatids and this may involve unconventional secretion pathways to accommodate this novel function for the acrosome.

GPP34, now called GOLPH3 (Golgi phosphoprotein 3), the first example of a Golgi resident oncogene protein, has a well-defined role in the regulation of Golgi ribbon structure (Buschman et al., 2015; Bergeron et al., 2017), and this property may also be shared with GRASP55 (Rabouille and Linstedt, 2016). During steps 1–7 spermatids, the Golgi apparatus is crescent in shape with the TGNs exposed to the nuclear surface of early spermatids (Au et al., 2015a). This would allow easy access of the proacrosomic granules to the nuclear surface to which they bind. Defining the shape of the Golgi ribbon may be in part the role of GPP34 and GRASP55, but this would be limited to its expression profile during a defined time point during spermatogenesis, i.e. steps 1–7 spermatids when both are expressed (Au et al., 2015a; Figs. 1F and 5).

Man2 α 1, ManIIX and LAMAN

Man2 α 1 and ManIIX are both well known Golgi mannosidases (Man). Man2 α 1 is a universal Golgi marker also localizing to Sertoli cells (Igdoura et al., 1999; Ramalho-Santos et al., 2001). ManIIX is a male germ cell specific mannosidase partially overlapping with Man2 α 1 in its specificity from steps 1–7 spermatids with both the Golgi and acrosome being reactive (Au et al., 2015a; Fig. 5). These sequence-related proteins likely have related functions in alpha mannosidase trimming of high mannose containing N-linked oligosaccharides during acrosome formation (Moremen, 2002; Herscovics, 1999; Rose, 2012).

LAMAN, also known as Man2B1, a major glycoprotein was also found in the Golgi apparatus and acrosome of steps 1–7 spermatids (Au et al., 2015a; Fig. 5). LAMAN is a ubiquitous lysosomal alpha mannosidase that cleaves alpha mannosidase linkages in glycans (Sun and Wolfe, 2001).

Segregation of Golgi Localized Proteins Exclusive to the Golgi Ribbon Versus Those Expressed in the Golgi Ribbon and Acrosome

During acrosome formation, 10 of the 14 Golgi proteins examined in this study localized to the Golgi apparatus of steps 1–7 spermatids (Au et al., 2015a). Of the 10, 6 i.e., GRASP55, GBF1, ManIIX, GPP34, Man2 α 1, and LAMAN localized to both the Golgi apparatus and developing acrosome (Au et al., 2015a). However, four Golgi proteins, i.e. GL54D, TM9SF3, TMED4/p25 and TMED7/p27, reacted only for the Golgi apparatus with no evidence of reactivity for the acrosome (Au et al., 2015a). Hence a segregation of proteins exists during acrosome formation, whereby some proteins are excluded from the acrosome but are present in the Golgi apparatus. Acrosome formation is often explained by the cisternal maturation model for Golgi biogenesis and traffic (Hermo et al., 2010b; Thorne-Tjomsland et al., 1988), however, the segregation of the four Golgi markers is not consistent with this model. In addition to the cisternal maturation model, other models have been proposed for Golgi traffic (Patterson et al., 2008; Dmitrieff and Sens, 2013; Lavieu et al., 2013; Dancourt et al., 2016; Mani and Thattai, 2016; Glick and Luini, 2011). Based on our observations the spermatid Golgi is well suited to examine the validity of these various models.

Postacrosome Period: Late Bloomers and Their Role in Late Spermatids: SORTILIN and ManIIX

After acrosome formation, the Golgi apparatus becomes spherical and positions itself in the cytoplasmic lobe of late spermatids. Coincident with the movement of the Golgi apparatus into the cytoplasmic lobe at step 8 spermatids, Golgi located immunogenicity of 12 proteins, i.e. GRASP55, GBF1, GPP34, ManIIX, Man2 α 1, and LAMAN was below detection (Au et al., 2015a). By contrast four Golgi proteins, i.e. GL54D, TM9SF3, TMED4/p25 and TMED7/p27 maintained reactivity into late spermiogenesis thus defining the identity of the Golgi apparatus in late spermatids (Au et al., 2015a; Fig. 5).

Two proteins revealed onset of expression at the late steps of spermiogenesis. Surprisingly, Golgi migration away from the acrosome also corresponded precisely with the onset of expression of sortilin in the Golgi apparatus at step 8 which continued till step 19 spermatids (Au et al., 2015a; Fig. 5). Sortilin transports lysosomal enzymes from the Golgi apparatus to MVBs and lysosomes (Braulke and Bonifacino, 2009). During acrosome formation trafficking from the Golgi apparatus to the developing acrosome appears to utilize mannose 6 phosphate receptors, as their RNA transcripts are prominent in early spermatids (O'Brien et al., 1994). However, from steps 8 onwards, the expression of sortilin likely represents its functions in plasma membrane remodeling (Clermont and Tang, 1985).

The Golgi is responsible for glycosylation (Zhang and Wang, 2016) and this occurs during acrosome formation with expression of Man2 α 1 and ManIIX. These sequence-related proteins likely have related functions in alpha mannosidase trimming of high mannose containing N-linked oligosaccharides (Moremen, 2002). The lack of detection of both of these proteins from steps 8–14 suggests a diminution in Golgi mannosidase activity that in turn would be linked to the well known major changes in N-glycosylation of proteins accounting for the high mannose and complex glycoproteins differentially expressed during spermatogenesis (Batista et al., 2012; Huang and Stanley, 2010). However, from steps 15–19, ManIIX expression returns with expression in the forming Hermes body (Au et al., 2015a; Fig. 5) likely heralding a return of complex sugar modification reactions on N-linked glycoproteins, with its expression being essential for spermatogenesis and male fertility (Fukuda and Akama, 2003a,b). In fact, terminal sugar incorporation in the Golgi apparatus has been well documented in late spermatids for glycoprotein synthesis destined for the plasma membrane (Clermont and Tang, 1985).

Exclusive Expression of Several Golgi Proteins During Formation of the Hermes Body at Step 19 Spermatids and Renewed Expression of Other Golgi Proteins Shut Down From Steps 8–18

At the last step of spermiogenesis, a resurgence of protein expression occurs at step 19 spermatids, with reactivity highlighting the forming Hermes body. Reactivity returns for TMED7/p27, which persisted till step 16, as well as GBF1, GPP34, Man2 α 1, LAMAN, which were shut down at step 8 (Au et al., 2015a; Fig. 5). In addition, two additional Golgi proteins became expressed for the first time, i.e. carboxypeptidase D (concentrated in the Golgi apparatus, where it functions by cycling to and from the plasma membrane (Breiner et al., 1998) and TMED2/p24 (Au et al., 2015a; Fig. 5). Although a stacked Golgi ribbon is no longer detectable at step 19, these proteins define the flattened membranous elements that congregate into the forming Hermes body as Golgi elements (Au et al., 2015a).

An important function of step 19 spermatids is in spermatid individualization into spermatozoa by disruption of the syncytium formed by intercellular bridges (Dym and Fawcett, 1971; Fabian and Brill, 2012; Greenbaum et al., 2009). It is attractive to propose the internal membranes (Golgi cisternae and vesicular transport) of the forming Hermes body as the source of new plasma membrane to seal off each individual spermatid resulting in spermatozoa.

The Hermes body of step 19 spermatids is maintained in epididymal sperm where its protein composition has been analyzed in detail by proteomics and localization studies. Au et al. (2015a,b) revealed that the flattened cisternal membranes of the forming Hermes body show marked differences in their Golgi protein composition from the Golgi apparatus of germ cells evolving during spermatogenesis, with some Golgi localized proteins not entering the Hermes body, i.e. GL54D, TMED4/p25, sortilin, TM9SF3 and GRASP55. In this way, the flattened cisternae of the step 19 spermatids appear to have different molecular constituents from the stacked Golgi cisternae of earlier germ cells, and this may be analogous to that postulated for functional individual yeast-flattened cisternae (Papanikou and Glick, 2009). In addition, cisternae of the step 19 spermatids may function independent of a stacked configuration as suggested for Golgi cisternae (Klumperman, 2011) and without the conventional setup of a continuous

Golgi ribbon. Thus, the Hermes body of epididymal sperm formed at step 19 spermatids appears to have evolved a system of unique flattened membranous cisternae unlike the conventional stacked Golgi apparatus to carry out specific functions for sperm maturation (Au et al., 2015a).

Proteins of Unknown Function

In the work of Au et al. (2015a), two abundant proteins of unknown function were identified as new Golgi markers (GL54D and TM9SF3). Moreover, over 200 other proteins of unknown function were uncovered in the isolated testis Golgi fraction, each of which may now be studied by future generations of scientists to elucidate their distribution and functions during germ cell differentiation.

Conclusion

The differential expression pattern of proteins related to the Golgi apparatus during germ cell development has been elucidated by incorporating knowledge of the stages of the cycle first described by Leblond and Clermont (1952). Their varied expression profile at select time points during germ cell differentiation strongly suggests diversified complex regulatory mechanisms that are in play to ensure the precise turning on and off of these proteins of different functions which are related to the diversified differentiation process of germ cells. The endpoint of spermiogenesis resulting in Hermes body formation in step 19 spermatids has also characterized and defined by a unique set of Golgi markers. The differential specific expression of novel and established Golgi markers during spermatogenesis may now help define a new model system to answer the unresolved questions in Golgi apparatus structure and function (Emr et al., 2009).

Acknowledgments

I hope that all aspiring young scientists early in their career would be so privileged as to have such great role models as I (LH) was with Dr. Y. Clermont and Dr. C.P. Leblond. I would like to thank Dr. Clermont my supervisor and mentor who challenged and inspired me over my 45 years at McGill University, as did Dr. Leblond. Their sincere dedication and love of science allowed me and generations of students to find our niche and aspire us to be as great as they were. I would also like to thank Dr. M.F. Lalli who assisted me as a graduate student in learning the ropes of electron microscopy, tissue fixation and preparation and spermatogenesis. This paper is dedicated to Yves Clermont and CP Leblond who elaborated the stem cell renewal theory for male germ cell differentiation. <http://www.mcgill.ca/anatomy/stem-cell-renewal-theory>.

Introduction: Background on the Formation and Constituents of the Hermes Body (Cytoplasmic Droplet)

The cytoplasmic droplet (CD) of sperm was first identified by Retzius (1909) more than a century ago, and over time it has been a lost soul in quest for an identity. The CD is a feature of epididymal sperm and corresponds to a small dilated bulge enveloping a focal area along the length of the sperm flagellum (Fig. 1). In the testis it is formed at the last step of spermatid development, a process defined as spermiogenesis, which in the rat is composed of 19 steps. At step 19 spermatids, the forming CD appears as a dilated area of the flagellum located at the connecting piece (neck), which anchors the head of the sperm to the flagellum (Fig. 1). These spermatids are ready to be released into the seminiferous tubule lumen whereupon they enter the epididymal duct. Hence the CD forms a distinct compartment of the flagellum with a unique setup of organelles that has eluded generations of scientists as to a functional significance.

During sperm transit through the epididymis, the CD slides along the mid piece of the flagellum, where mitochondria are arranged in a spiral manner, to the annulus, a ring-like structure separating the mid piece from the principal piece of the

Fig. 1 Schematic representation of the forming cytoplasmic droplet (recently renamed the Hermes body) at step 19 spermatid in the testis and fate of the CD as sperm transit through the epididymis. At step 19 spermatids, the forming cytoplasmic droplet appears as a dilated area of the flagellum located at the connecting piece (neck), which anchors the head of the sperm to the flagellum. The bulk of cytoplasm of the step 19 spermatid forms the residual body, which is phagocytosed and degraded by Sertoli cells of the seminiferous epithelium. The step 19 spermatids are released as spermatozoa from the seminiferous tubule lumen whereupon they traverse the epididymal duct. As sperm enter the initial segment of the epididymis, the cytoplasmic droplet is still located at the neck area of the flagellum. During sperm transit through the caput to the corpus region of the epididymis, the cytoplasmic droplet slides along the mid piece of the flagellum, where mitochondria are arranged in a spiral manner, to the annulus (An), a ring-like structure separating the mid piece from the principal piece of the flagellum. Thereafter the cytoplasmic droplet detaches from the flagellum to be liberated into the epididymal lumen, whereupon it fragments with its contents being taken up by the epithelial clear cells. Diagram drawn by Dr. Yves Clermont. Figure taken from Hermo L, Dworkin J, Oko R. (1988). Role of epithelial clear cells of the rat epididymis in the disposal of the contents of cytoplasmic droplets detached from spermatozoa. *The American Journal of Anatomy* **183**, 107–124. Reproduced with permission of Wiley and sons.

flagellum (Hermo et al., 2010) (Fig. 1). In some species, the CD detaches from the flagellum and is liberated into the lumen whereupon it fragments and releases its contents, which are then taken up by the epithelial clear cells of the epididymis (Hermo et al., 1988) (Fig. 1). As sperm traverse the epididymis, they acquire their maturational features, motility and fertility (Orgebin-Crist, 1969), an event coincident with the presence of the CD on sperm suggesting a cause-effect relationship (Hermo et al., 1988, 2010). Moreover, the CD is an evolutionarily conserved structure unique to epididymal spermatozoa where it has been observed in over 30 vertebrate species from fish to primates and humans (Yuan et al., 2013) suggesting a functional role for sperm.

Early biochemical studies identified activities of lysosomal hydrolases and glycolytic enzymes in CDs of several species (Dott and Dingle, 1968; Roberts et al., 1976; Moniem and Glover, 1972). As first revealed with the advent of the electron microscope (EM), the most conspicuous features of the CD were numerous short flattened as well as dilated membranous profiles suggested to be remnants of Golgi and ER cisternae (Bloom and Nicander, 1961; Fawcett and Ito, 1965). Later studies revealed that the numerous short flattened membranous profiles appeared to resemble the Golgi cisternae of the Golgi stack. However, unlike cisternae of the Golgi apparatus, these cisternae did not form a typical stacked configuration and were unreactive for various Golgi cytochemical markers (Hermo et al., 1988) (Fig. 2). The identity of the cisternae awaited more sophisticated techniques.

As will become apparent in the present article, the current data from the literature suggest that sperm themselves through the CD also play a role in their own maturation (Au et al., 2015b; Yuan et al., 2013), a function previously ascribed mainly to the epithelial epididymal cells (Robaire and Hermo, 1988; Cornwall, 2009). By its protein and organellar makeup the CD appears to regulate the initiation of sperm motility, a prerequisite for sperm maturation. In the literature confusion exists about the CD a structure formed by a normal testis, versus excess residual cytoplasm (Aitken et al., 1994) denoting a structure found on abnormally formed sperm liberated from a testis displaying damage to the seminiferous epithelium (review Cooper, 2005). As a consequence of this confusion, the term Hermes body (HB), the winged messenger of the Greek gods, transforming the mortal to the immortal was proposed to identify the true CD (Au et al., 2015b). In the reproductive context, the presence and functions of the HB along the mid piece of sperm during epididymal transit, where sperm mature, represents a transformation of sperm from an immotile unfertile to a motile fertile state.

Sweetening up the Sperm by Glycolysis: A Major Function of the Hermes Body

In order to determine a functional role for the HB of sperm, a method to isolate fractions of isolated HBs of adult rat caput epididymal sperm was developed with proteins characterized by quantitative tandem mass spectrometry (Au et al., 2015b). From the 1511 proteins identified in the isolated HB fraction, a selection of proteins was analyzed with antibodies to reveal by light microscope (LM) immunohistochemical (IHC) and immunofluorescence (IF) their localization to the sperm HB of in situ epididymal tissue sections. Here we will focus on some of the proteins in the life history of the HB from the work of Au et al. (2015b) that appear to serve a role in the maturation process of sperm.

Fig. 2 Electron micrograph of tangential sections through the CD of caput epididymal sperm. Short flattened cisternal elements are abundant (large arrowheads) with some being straight, while others are curved. They congregate together in one pole of the cytoplasm of the CD. Many small vesicles (small arrowheads) are evident some in close proximity to the cisternae. The edges of the cisternae (curved arrows) are often contiguous with one another and the plasma membrane. M, mitochondria; ODF, outer dense fibers. Original Mag 48,750 $\times$.

Out of the 1151 detected proteins, the plasma membrane protein, glucose transporter 3 (GLUT3) (Solute Carrier Family 2 Facilitated Glucose Transporter Member 3) was the most abundant protein of the isolated HB of rat epididymal sperm. This along with the finding that Hexokinase1 was the second most abundant protein provided the first clue as to the function of this elusive structure in providing ATP via glycolysis to sperm. This conjecture was further supported by the characterization of proteins of the entire glycolytic pathway to the isolated HB by proteomics and also by the LM-IHC visualization of GLUT3 (**Fig. 3A**), HEX1 (**Fig. 3B**) and sperm-specific lactate dehydrogenase C to this structure in situ (**Au et al., 2015b**). During epididymal sperm maturation, ATP generation from glycolysis appears to direct the initiation of sperm motility (**Mannowetz et al., 2012; Miki, 2007; Odet et al., 2013**). However, while several investigators localized glycolytic enzymes to the mid piece and/or principal piece of the sperm flagellum, (**Tanii et al., 2007; Eddy et al., 2003; Miki, 2007; Ford, 2006; Nakamura et al., 2010**), the LM-IHC/IF and proteomic observations of **Au et al. (2015b)** emphasized the concentration of glycolytic enzymes and relevance of glycolysis in the HB of epididymal sperm.

Previous proteomics studies on whole sperm (**Baker et al., 2013; Chocu et al., 2012; Chauvin et al., 2012**) uncovered GLUT-3 and other glycolytic metabolic enzymes as prominent. In humans, 436 proteins of the 1056 found in sperm belonged to various metabolic pathways, with glycolytic proteins being the highest expressed (**Baker and Aitken, 2009**). Proteomic analyses on proteins from enriched purified HBs from murine epididymal spermatozoa identified 105 proteins, 71 (68%) of which were enzymes involved in energy metabolism (**Yuan et al., 2013**). ATP generation has long been established as a requirement for sperm motility. The findings of **Au et al. (2015b)** and **Yuan et al. (2013)** that enzymes of the glycolytic pathway are enriched in the HB proposes a function for this structure in the initiation of sperm motility by ATP generation that is a prerequisite for sperm maturation as they transit through the epididymal duct.

Also relevant was the finding of Monocarboxylate Transporters (MCT) in the Hermes body. These utilize proton gradients to move molecules with one carboxylate group such as lactate or pyruvate across the plasma membrane. MCT1 and MCT2 localized to the Hermes body of epididymal sperm (**Figs. 3C and D**).

Internal Flattened Cisternae of the Hermes Body Reveal Golgi Proteins Differing From That of Germ Cells of the Testis

A clue as to the composition and functions of the HB came in 1993, when Oko et al. provided evidence by EM that the flattened internal membranes corresponded to intact Golgi cisternae. Indeed at the last steps of spermiogenesis (steps 15–18), it was noted that flattened Golgi cisternae that constituted the Golgi stack separated from each other and gradually became free floating

Fig. 3 A–D: LM photomicrographs of sections of the epididymal duct immunostained with antibodies to: GLUT3 (**Fig. 3A**), HEX1 (**Fig. 3B**), MCT1 and MCT2 (**Figs. 3C and D**). The Hermes body of epididymal sperm are reactive (*arrows*) with each appearing as a small dilated area along the flagellum. Lu, lumen; P, principal cells; IT, intertubular space.

in the spermatid cytoplasm (Fig. 4). At the last step of spermiogenesis, i.e., step 19 (stage VIII of the cycle; Leblond and Clermont, 1952), these Golgi elements congregated into the forming HB, as loosely organized unstacked cisternae (Okamoto et al., 1993) (Fig. 4). Confirmation that the HB of epididymal sperm contained Golgi proteins and cisternae was demonstrated by western blots and in situ immunoreactivity for the Golgi markers TGN38, alpha 2, 6 sialyltransferase and beta 1, 4 galactosyl transferase

Fig. 4 Schematic representation of the fate of the Golgi apparatus of spermatids and formation of the cytoplasmic droplet (CD), recently renamed the Hermes body, at step 19 of spermiogenesis of the adult rat testis. In early spermatids the Golgi apparatus (G) is hemispherical and forms the acrosomic system (AS) overlying the nucleus (N) as seen at step 7. At step 10 spermatids, the Golgi is spherical and shifts from an acrosomic position to the cytoplasmic lobe (CL). By step 18 the Golgi apparatus has fragmented resulting in dispersal of the individual flattened Golgi cisternae (sacculi, S) into the cytoplasmic lobe. At step 19, the Golgi cisternae enter the forming CD located at the neck area of the flagellum. Other organelles (ER, mitochondria, lipid) enter the residual body of the step 19 spermatids, which is larger in size and destined to be phagocytosed and degraded by the Sertoli cells of the seminiferous epithelium (Morales et al., 1985). After being released from the seminiferous epithelium, the step 19 spermatids (spermatozoa) pass through the efferent ducts (EDs), initial segment (IS), caput, corpus and cauda regions of the epididymis. While the CD is situated at the neck area of the flagellum in the IS, it migrates along the flagellum to the annulus (An) which demarcates the site where the mid piece of the flagellum becomes the principal piece. This occurs by the time spermatozoa enter the caput region of the epididymis. By the time spermatozoa enter the cauda epididymidis, some of the CDs liberate themselves from the sperm flagellum. RT: rete testis; Tubule: seminiferous tubule. Diagram drawn by Dr. Yves Clermont. Figure taken from Okamoto, R., Hermo, L., Chan, P.T., Fazel, A. and Bergeron, J.J. (1993). The cytoplasmic droplet of rat epididymal spermatozoa contains saccular elements with Golgi characteristics. *The Journal of Cell Biology* 123(4), 809–821. Reproduced with permission of The Journal of Cell Biology.

(Oko et al., 1993). By LM-IF, Moreno et al. (2000a, b) localized the Golgi markers giantin, Golgin-97, Golgin95/GM130, Golgin160 and GRASP65 (Moreno et al., 2000a, b) to the HB of isolated epididymal sperm.

In order to determine the validity of this Golgi hypothesis, a method was devised to isolate the Golgi apparatus of germ cells of the testis to elucidate which Golgi proteins were expressed during germ cell differentiation, as well as those that were maintained in Golgi cisternae of the forming HB of step 19 spermatids and the HB of epididymal sperm. By quantitative proteomics a total 1318 were uncovered by Au et al. (2015b). From these 20 were examined by LM-IHC/IF. The data on protein composition of the Golgi cisternae of the HB revealed that many of the proteins localized to the Golgi of germ cells during their differentiation process, such as GL54D, TM9SF3, TMED4/p25, MG160, GRASP55, Sortilin, and UBXD8, were completely absent from the forming HB and that of epididymal sperm (Au et al., 2015a).

However, a host of Golgi proteins of different functions resided in the HB, of which TMED7/p27 was abundant by proteomics and as seen by LM-IHC of in situ HBs of epididymal sperm (Fig. 5A). Other Golgi proteins such GBF1, GPP34, LAMAN, Man2 α 1, MANIX, TMED2/p24 and carboxypeptidase D (Breiner et al., 1998) also resided in the HB as revealed by proteomics and LM-IHC (Au et al., 2015b). Hence even though a Golgi stack is no longer detectable in the HB, these proteins define the flattened membranous elements that congregate therein as Golgi cisternae but differing in protein composition from that of germ cells. Moreover, even the expression profiles of different Golgi proteins expressed by germ cells differed during the various phases of their differentiation process (Au et al., 2015a). Also see review of Hermo et al. (2018).

Figs. 5 A–F: LM photomicrographs of sections of the epididymal duct immunostained with antibodies to: TMED7/p27 (Fig. 5A), and BIP (Fig. 5B); ERP57 (Fig. 5C), annexin 6 (Fig. 5D), Vps13c (Fig. 5E). Hermes bodies of sperm are reactive in the epididymal lumen (arrows). Fig. 5F: LM photomicrograph of a testicular section immunostained with anticarboxypeptidase D antibody illustrating reactive forming Hermes body situated at the neck region of the flagellum (curved arrows) of the step 19 spermatids at stage VIII of the cycle. Lu, lumen; P, principal cells; IT, intertubular space.

In this way, the flattened cisternae of the step 19 spermatids appear to have different molecular constituents from those of a stacked Golgi apparatus and this may be analogous to that postulated for individual yeast-flattened cisternae (Losev et al., 2006; Papanikou and Glick, 2009). In addition, these cisternae may function independent of a stacked configuration as suggested for Golgi cisternae (Klumperman, 2011) and without the conventional setup of a continuous Golgi ribbon. A similar situation exists in circulating platelets where Golgi proteins are present as nonstacked, scattered, separate structures, with selective sets of Golgi enzymes being secreted during platelet activation (Yadav et al., 2017). Thus, the Hermes body of epididymal sperm formed at step 19 spermatids appears to have evolved a system of unique flattened membranous cisternae unlike the conventional stacked Golgi apparatus to carry out specific functions related to sperm maturation (Au et al., 2015b). The specific role(s) of the flattened cisternae of the HB has yet to be resolved thoroughly and awaits the minds of curious young investigators.

Function of the Golgi Cisternae in Relation to the Size of the Hermes Body and Enhancing Glycolysis

A consistent observation by EM of the HB of step 19 spermatids and epididymal sperm was the presence of numerous small 50-60 nm vesicles that associated with the flattened Golgi cisternae (Fig. 2). These appeared to bud off not only at the edges but also from their mid regions. A role for these vesicles comes from EM observations of cryo-fixed in situ HB of epididymal sperm using anti-TMED7/p27 and GLUT3 antibodies. With the former, gold particles localized over the flattened Golgi cisternae of the HB in greater numbers than that over the plasma membrane, while the reverse was the case for GLUT3 (Au et al., 2015b). Thus TMED7/27 Golgi derived vesicles may traffic GLUT3 to the surface of the Hermes body.

Validity for this hypothesis comes from an LM quantitative analysis of the size of the forming HB at step 19 spermatids versus that seen of the HB of sperm in the initial segment of the epididymis. Hermes bodies of step 19 spermatids appeared to be smaller than those of the Hermes body of epididymal sperm of the initial segment (compare Fig. 6A with B). Also the size of the Hermes body of the latter appeared to be larger in size as compared to those of epididymal sperm of the caput/corpus/cauda epididymidis (compare Fig. 6B with C).

This was confirmed by quantitative analysis of the mean transverse diameter (at its largest axis) of the forming Hermes body of step 19 spermatids with those of epididymal sperm of the initial segment and cauda epididymidis. The mean transverse diameter of atlastin 3 reactive forming Hermes bodies of step 19 spermatids was 2.914 μm with a standard deviation of ± 0.160 . The mean transverse diameter of atlastin 3 reactive Hermes bodies measured in the initial segment of the epididymis was 3.558 μm with a standard deviation of ± 0.348 . An unpaired *t*-test at the 95% confidence interval revealed that the difference was statistically significant (*P*-value < 0.0001). Moreover, the mean transverse diameter of atlastin 3 reactive Hermes bodies measured in the cauda epididymidis was 2.335 μm with a standard deviation of ± 0.202 . An unpaired *t*-test at the 95% confidence interval revealed that the difference was statistically significant (*P*-value < 0.0001) from that of the initial segment. The size of the HB of caput epididymal sperm was also significantly reduced as compared to the initial segment.

Hence a proposed function for the Golgi cisternae may be to traffic Golgi derived vesicles to the cell surface for enhancing the size of the HB. Thus TMED7/p27 may traffic vesicles carrying GLUT-3 to the surface of the HB to serve 2 purposes: to add additional plasma membrane to the cell surface of the HB to increase its size, which in turn would add GLUT3 for purposes of increasing uptake of glucose for increased ATP production for initiation of sperm motility which occurs in the proximal region of the epididymal duct.

Endoplasmic Reticulum (ER), Endosomes, COP Coats, Clathrin, SNAREs, Annexins, AAA + Proteins and GTPases Function in Vesicular Trafficking and Membrane Fusion in the Hermes Body

The proteomic study of Au et al. (2015b) also revealed many ER-related proteins in the HB. ER proteins involved in protein folding included BIP (Fig. 5B) an ER HSP70 family member, also known as glucose-regulated protein 78 or HSPA5, and the glycoprotein

Figs. 6 (A) LM photomicrograph of a testicular section immunostained with anti-atlastin 3 antibody illustrating reactive forming Hermes body of step 19 spermatids at stage VIII of the cycle (*curved arrows*). (B and C) LM of Hermes bodies of epididymal sperm (*arrows*) of the initial segment and caput epididymidis reactive for atlastin 3 antibody. The size of the Hermes body appears to be largest for epididymal sperm of the initial segment. Lu, lumen; P, principal cells; IT, intertubular space.

folding enzyme, ERP57 (Fig. 5C). The glycoprotein folding sensor glucosyl transferase UGGT, the diglucose lectin malectin, and calnexin, the ER lectin chaperone, were also evident.

A striking morphological feature of the HB was the preponderance of flattened cisternae largely unstacked but with an extreme curvature at their edges. The membrane curvature and tubulation proteins, such as atlastin 1, 2, and 3 (Fig. 6B and C) (Hu et al., 2009; Orso et al., 2009) and reticulon 1 and 3 (Chen et al., 2013) were evident in the HB and as such were implicated (Au et al., 2015b).

Protein synthesis proteins via the 68 characterized ribosomal proteins, were characterized by proteomics, as was the abundant ribosome-associated ELONGATION FACTOR 1 ALPHA 1 (EF1A1) along with EF2 (Au et al., 2015b).

Not only were Golgi and ER proteins noted in the HB, but also ER to Golgi, Golgi to ER and endosome to Golgi trafficking proteins (Au et al., 2015b). All seven subunits of COPI coatomer were found in the HB predicting retrograde membrane trafficking (Brandizzi and Barlowe, 2013). Anterograde trafficking COPII coatomer subunits were represented by the GTPase activating protein, sec23, a coat component of COPII vesicles. The coat protein CLATHRIN HEAVY CHAIN (CHC) and the clathrin adaptors AP1 (CLATHRIN ADAPTIN-1) and AP2 (CLATHRIN ADAPTIN-2) were also characterized (Au et al., 2015b).

Proteins suggesting an active role of the HB in membrane fusion were represented by annexins (Fig. 3D), the AAA proteins p97, NSF and its associated alpha SNAP. The endosome to Golgi R SNARE, VAMP 3 (vesicle associated membrane protein 3, also known as cellubrevin), its partner the GTP-binding protein RAB14 (Gonzalez and Scheller, 1999; Junutula et al., 2004), and the Q-SNARE, SYNTAXIN-13 were suggestive of endosomes in this structure and as confirmed by EM observations of large membrane bound vesicular structures in the HB of in situ epididymal sperm (Au et al., 2015b).

The most abundant GTPase was IQGAP known to coordinate actin polymerization and microtubule formation (Watanabe et al., 2004). This may be needed for the known migration of the Hermes body along the mid piece of the flagellum (Cooper, 2011), although a role in signaling (Smith et al., 2015) to coordinate membrane trafficking with glycolysis may also be considered. The most abundant Rab of the GTPase category was Rab14 (Au et al., 2015b), known to be involved in the trafficking and internalization of the GLUT3 paralog, GLUT4, in other cell types (Sadacca et al., 2013).

Taken together, the abundance and localization of these membrane fusion and trafficking proteins with the localization of GLUT3 to the surface and TMED7/p27 to the internal Golgi membranes of the HB is consistent with GLUT3 trafficking to regulate glucose uptake and glycolysis for ATP production and initiation of sperm motility. Yet the full extent of the functions of the proteins of the HB is in dire need of investigation.

Movement of the Hermes Body Along Sperm Flagellum During Epididymal Transit

The HB of epididymal sperm moves in a peristaltic-like manner along the mid piece of the flagellum from the neck to the annulus as sperm move from the caput to the cauda epididymidis (Fig. 1), while the internal organellar membranes rotate in a vortex manner around the axoneme and mitochondrial sheath (Hermo et al., 2010; Cooper, 2011; Sadacca et al., 2013).

Movement of the HB along the mid piece varies between species. Peristaltic motions of the smooth muscle, myoid cells, positioned as several concentric layers at the outer wall of epididymal tubules (Oliveira et al., 2016), has been suggested for some species, as the application of repeated or sustained centrifugal force mimics this function (Cooper, 2005). In the guinea pig, formation of thin filaments cross linking the plasma membrane and outer mitochondrial membranes in the area of the HB appear to function in squeezing it along the midpiece distally to the annulus (Suzuki-Toyota et al., 2010). Such a network of filaments has not been noted in the rat, however, actin and myosin were noted in a proteomic study of the HB of rat epididymal sperm and represent candidates to regulate this movement (Au et al., 2015b). An additional function for the actin based motility system and the characterized myosin motors of the HB would be for active mixing of cytosolic metabolites (Zimmermann et al., 2012), such as ATP for initiating sperm motility.

Role of Hermes Body in Osmolality Regulation

Various studies have pointed to a potential role of the HB in regulating its volume by allowing water entrance/exit and uptake of epididymal osmolytes (Cooper et al., 2004; Fetic et al., 2006). This would allow spermatozoa to adapt to osmolality changes and maintain membrane integrity during their transit through the epididymis and through the female reproductive tract, because when spermatozoa are challenged with low osmolality, the flagellum of epididymal spermatozoa becomes coiled at the position of the HB (Cooper, 2007). As suggested by Cooper (2011), the volume of the Hermes body may be a consequence of the presence of the highly abundant aquaporin water channels localized to this structure (Hermo et al., 2008; Chen et al., 2011). In fact, defective water channels and volume regulation results in swelling and initiation of angulation of the flagellum at the HB leading to a hairpin bend morphology (Yeung et al., 2009). This phenomenon can also be mimicked by blocking cation and anion channels involved in volume regulation (Yeung et al., 2002, 2005; Barfield et al., 2005; Cooper et al., 2004), with sperm failing to reach the oviduct resulting in infertile mice (Yeung et al., 2000; Cooper et al., 2004).

Taken together with the prior localization of the highly abundant water channel aquaporin 7 to the Hermes body in situ (see Fig. 2C of Hermo and Smith, 2011), then the Hermes body represents an expanded aqueous environment segregated from

the rest of the more compacted intracellular environment of the sperm flagellum (Hermo and Smith, 2011). This would enable reversible protein-protein interactions and the ready diffusion of metabolites.

Cholesterol Removal and Internal Membranes of Hermes Body

A striking morphological feature of the Hermes body is the preponderance of flattened cisternae largely unstacked but with an extreme curvature at their edges. The membrane curvature and tubulation proteins, such as atlastins (Fig. 6) and reticulons (Chen et al., 2013), localized to the HB and as such are implicated. A further feature of the flattened cisternae is the close proximity of their curved edges to each other but also with that of the plasma membrane (Oko et al., 1993) (Fig. 2). The latter apposition may be relevant to lipid remodeling of epididymal sperm (Helle et al., 2013; Levine, 2004) especially for cholesterol removal which coincides with sperm transit through the epididymis and which is essential for sperm fertility (Saez et al., 2011).

Fate of the Hermes Body of Epididymal Sperm

The release and fate of the HB during epididymal transit appears to be species dependent. In the rat and monkey, HBs detach from spermatozoa by the time they reach the cauda epididymidis (Xu et al., 2013; Hermo et al., 1988, 2010), but a more recent study suggested that many HBs retain them in the cauda epididymidis (Au et al., 2015b). In the mouse, bull, boar, ram, and goat, the HBs remain on spermatozoa in the epididymis and are not released until the time of ejaculation (Cooper, 2005; Cooper and Yeung, 2003; Xu et al., 2013).

In bovine ampulla vas deferens and seminal vesicle, a haemolytic phospholipid binding protein has been suggested to liberate HBs from sperm (Matousek and Kysilka, 1980; Matousek and Kysilka, 1984), with fructose functioning in this capacity in boars (Harayama et al., 1996; Temple-Smith, 1984).

During sperm maturation in the brushtailed possum, HBs were shed from maturing spermatozoa in the caput region of the epididymis. Disappearance of detached HBs from the lumen was associated with a region of specialized principal cells, which selectively sequestered and phagocytosed them from the epididymal lumen (Temple-Smith, 1984). These observations contrasted the rat where after detaching from the flagellum, the HBs appeared to fragment in the epididymal lumen with their contents taken up by the epithelial clear cells (Fig. 1) (Hermo et al., 1988).

Does the Presence of the Hermes Body Affect Sperm Fertility

Failure to properly form or shed the HB has been associated with male infertility. Male *Alox15* mice lacking the organelle degradation enzyme 15-lipoxygenase (15LOX) displayed sperm HB anomalies (Moore et al., 2010). There were more sperm with attached HBs in the cauda region as compared to wild type mice and presence of isolated, intact mitochondria not noted in wild type HBs. These findings may explain the reduced fertility and smaller litter size of *Alox15* mice.

Spermatid maturation 1 (*Spem1*) encodes a protein exclusively expressed in the cytoplasm of steps 14–16 mouse elongated spermatids. Male mice deficient in *Spem1* were completely infertile because of deformed sperm characterized by aberrant HBs located in atypical positions and deformed flagella (Zheng et al., 2007).

The majority of *Tnp1*-null and *Tnp1-Hils1* double KO spermatozoa were mostly devoid of HBs. *Tnp1* encodes transition protein 1 (TNP1) and *Hils1* encodes a histone variant specifically expressed in elongated spermatids (HILS1). *Tnp1* KO male mice were sub-fertile, while *Tnp1-Hils1* double KO male mice were infertile (Zheng et al., 2007).

There have also been reports that the retention of HBs on sperm in domestic animals is associated with infertility (Amann et al., 2000; Thundathil et al., 2001; Kuster et al., 2004). However, in humans the majority of motile sperm found in the ejaculate bear a HB, which differs in its position from other species, being at the neck region rather than the annulus (Cooper, 2005). Their persistence does not appear to be an abnormal feature of human sperm, as HBs are not deleterious to sperm motility and may be related to physiological volume regulation (Cooper et al., 2004; Fetic et al., 2006). This may reflect their short mid piece obviating droplet migration and flagellar angulation and hampering droplet loss (Cooper, 2011).

A recent case report has shown that live births resulted from two separate IVF cycles in a couple in which ICSI was performed with sperm specifically selected for presence of small cytoplasmic droplets. Cycles using standard sperm selection methods resulted in very poor embryo development and no pregnancies (Bellish et al., 2015).

Selective Protein Loss in the Hermes Body: Proteasomes and Proteins Involved in Degradation

The concentration of ubiquitin, all subunits of the proteasome, the ATPase P97 linked to protein translocation in ERAD to the proteasome, and the highly abundant known germ cell ubiquitin ligase cullin3 (Wang et al., 2006), the stress response sperm ubiquitin

ligase (Genschik et al., 2013; Wang et al., 2006) appeared to explain the selective and progressive loss of 12 of the 43 proteins of the Hermes body as sperm proceeded from the initial segment to the cauda epididymidis (Au et al., 2015b). However, their presence also suggests a role for the abundance of glycolytic enzymes in the Hermes body, i.e., to generate ATP for protein degradation. Proteasome subunits and ubiquitin conjugating enzymes have also been characterized in a proteomic study of whole epididymal sperm (Chauvin et al., 2012). Localization studies of ubiquitin-proteasome pathway and 15-lipoxygenase (15LOX) (Moore et al., 2010) confirmed their presence in the HB in situ for sperm maturation (Hou and Yang, 2013).

The Hermes Body Compartmentalizes Stress Proteins

Intracellular antioxidant proteins are involved in protecting sperm against oxidative stress (Robaire et al., 2006; Hermo et al., 2010; Moore et al., 2010). Peroxiredoxins 1, 3 and 6 noted in sperm (O'flaherty and De Souza, 2011) and which scavenge reactive oxygen species, were abundant in the HB, as well as glutathione peroxidase and transglutaminase (Au et al., 2015b). Glutathione S transferases were noted by proteomics in the isolated HB (Au et al., 2015b), and by LM-IHC in previous studies (Veri et al., 1993; Papp et al., 1995).

Eighteen different heat shock proteins protective against stress were also evident in the HB (Au et al., 2015b). This included the germ cell specific HSP70.2 protein, HSP70.3 and HSP86. The HSP70 ER luminal protein, GRP170 was also abundant. Thus the Hermes body contains proteins that provide protection of whole sperm from oxidative stress (Aitken et al., 2014).

Step 19 Spermatids: Formation of the Hermes Body

While the proteomic data characterized proteins to the HB of epididymal sperm, a striking observation was made when these proteins were analyzed as they evolved during the course of germ cell differentiation. A burst of both non Golgi and Golgi protein expression was prominent exclusively in step 19 spermatids during formation of the HB (Au et al., 2015a, b; Hermo et al., 2018). These included AnnexinA1, AP1 and AP2, malectin, atlastin 2, syntaxin 13, Vps13c (member of the Vps13 family of vacuolar protein sorting-associated proteins), tubulin, peroxiredoxins 1 and 6, and the monocarboxylate transporter MCT2, all of which were also present in the HB as sperm entered the proximal region of the epididymis (e.g., Vps13c, Fig. 3E and MCT2, Fig. 3D). This also conformed with expression selectively to step 19 spermatids for the Golgi proteins TMED2/p24 and carboxypeptidase D (Fig. 3F). This has been also noted for several GSTs that became expressed solely at step 19 (Papp et al., 1995). Thus step 19 spermatids appear as highly active cells for protein expression contrary to dogma. This makes the forming Hermes body a site of major expression of proteins that had not been reported in any earlier studies and which may serve an important role in sperm as they leave the seminiferous tubule lumen and traverse the epididymis (Au et al., 2015b).

Since transcription ceases immediately at the end of acrosome formation by step 8 (Monesi, 1965), then the differential expression of the Golgi and non Golgi proteins after step 8 must necessarily reflect translational regulation as described for many other proteins during late spermiogenesis (Hecht, 1990). Transcriptional regulation of changes in the structure and function of organelles of the secretory pathway is well established in somatic cells (Schroder and Kaufman, 2005). Thus the translation controlled pathway for organelle modification and morphogenesis of germ cells (Chappell et al., 2013) must be prominent at step 19 in the formation and eventual function of the HB as it persists on sperm as they travel through the epididymis.

Proteins of Unknown Function

215 proteins of unknown function were also characterized by proteomics in the isolated Hermes body by Au et al. (2015b). Information on these proteins should extend considerably the role of this micro-compartment in epididymal sperm maturation.

Conclusion

As seen by EM, the forming Hermes body in step 19 and of epididymal sperm concentrates isolated flattened cisternae defined as Golgi elements, as well as dilated irregularly shaped membranous profiles suggestive of being ER and endosomes. Taken together with protein markers, this heterogeneity is indicative that the HB is a macromolecular structure enriched with subsets of endosomal, Golgi, coat and ER proteins for functions in membrane traffic and stress proteins for protection and proteins involved in degradation, as well as cytoskeletal elements for migration and a concentration of cytoplasmic proteins for glycolysis (Fig. 7). A detailed analysis of the expression profiles of germ cell Golgi and non-Golgi proteins and their overlapping distribution profiles can be found in our recent review (Hermo et al., 2018).

The HB is conserved amongst all mammalian species. The current data indicate that sperm themselves through the HB may play a role in their own maturation. Taken together with the proteins of the biosynthetic secretory apparatus characterized by Au et al.

Fig. 7 The initial segment and caput epididymidis of adult rats were dissected free from the testis and surrounding fat. A method was developed to isolate fractions of isolated HBs from epididymal sperm of these regions (Oko et al., 1993). Proteins were characterized by quantitative tandem mass spectrometry (Au et al., 2015b). From the 1511 proteins identified in the isolated HB fraction, 43 proteins were selected and analyzed with antibodies to reveal their localization by light microscope immunohistochemical (IHC) and immunofluorescence (IF) to the HBs of sperm of in situ epididymal tissue sections. The data revealed that the HB is involved in glycolysis, migration along the flagellum, membrane trafficking and protein degradation.

(2015b) and Chauvin et al. (2012) then far from being a cell devoid of a translational machinery, epididymal sperm may be reassessed as in a dynamic state of protein turnover as proposed for all cells (Schoenheimer, 1942).

Acknowledgments

I hope that all aspiring young scientists early in their career would be so privileged as to have such great role models as I (LH) was with Dr. Y. Clermont and Dr. C. P. Leblond. I would like to thank Dr. Clermont my supervisor and mentor who challenged and inspired me over my 45 years at McGill University, as did Dr. Leblond. Their sincere dedication and love of science allowed me and generations of students to find our niche and aspire us to be as great as they were. I would also like to thank Dr. M. F. Lalli who assisted me as a graduate student in learning the ropes of electron microscopy, tissue fixation and preparation and spermatogenesis. This article is dedicated to Yves Clermont and CP Leblond who elaborated the stem cell renewal theory for male germ cell differentiation. <http://www.mcgill.ca/anatomy/stem-cell-renewal-theory>.

Glossary

Chromatin A complex composed of proteins and nucleic acid that serves to package and regulate the genetic material.

Histone A group of small, highly conserved, basic proteins that package DNA in most eukaryotic cells.

Nucleosome A complex composed of four different histone proteins and associated DNA.

Protamines Spermatogenesis-specific, small, basic proteins, which package DNA in late stage spermatids and mature spermatozoa.

Spermatid A postmeiotic male germ cell.

Spermatocyte A meiotic male germ cell.

Spermatogonium A premeiotic, mitotically dividing male germ cell.

General Introduction to Chromatin Composition and Structure

Germ cells, like somatic cells, package their DNA into chromatin, a complex of proteins and nucleic acids that serves to regulate DNA sequence accessibility and ultimately control processes such as gene transcription, recombination, DNA repair, and genome stability. The primary protein constituents of chromatin are histones, small highly basic DNA packaging proteins. Histone proteins are generally ultra-conserved within eukaryotes, for instance they show no amino acid sequence divergence between mice and humans. The basic unit of chromatin, the nucleosome, consists of two pairs of four different histone proteins around which 146 bp of DNA is wrapped (Cutter and Hayes, 2015). (See Fig. 1).

Histone proteins are extensively posttranslationally modified with a variety of chemical modifications including methylation, phosphorylation, and acetylation (among many others). These modifications control the affinity of the histone proteins for DNA, as well as serving as a signaling platform for interaction with modification-specific binding proteins. These interactors, called chromatin readers, can then recruit additional modifying enzymes or transcriptional machinery to induce changes in gene expression. Modifications of histones occur in a variety of combinations and correlate highly with specific genomic localization and transcriptional activity. For instance tri-methylation of different lysine residues on the N-terminus of histone H3 associate with either

Fig. 1 Chromatin structure. (A) Schematic representation of a nucleosome, the basic unit of chromatin. DNA wraps around the four pairs of histone proteins (H2A, H2B, H3, and H4). (B) Representation of local chromatin structure. 147 bp of DNA is wrapped around each nucleosome with a short stretch of linker DNA between adjacent nucleosomes. (C) Model for the role of posttranslational modifications in chromatin. The N-termini of the different histone proteins are extensively modified. These modifications are recognized by chromatin readers, which in turn recruit interacting proteins to drive changes in transcription and other chromatin-mediated functions. Amino acid variations between N-termini of canonical H3.1/H3.2 and variant H3.3 and H3t proteins are indicated.

transcriptional activity or transcriptional repression, while presence of both modifications is suggested to represent a “poised” state capable of establishing either permanent activation or silencing following differentiation cues (Bernstein et al., 2006). The number of different modification states on different histone amino acid residues has led to the model of a “histone code,” wherein different combinations of histone modifications provide regulatory information on top of genetic sequence-encoded information to establish the gene regulatory landscape of a particular cell type (Jenuwein and Allis, 2001).

While canonical histone proteins are highly conserved, there exist within the mammalian genome several genes encoding variant histone proteins containing a small number of amino acid substitutions (Zink and Hake, 2016). Many of these histone variants are specifically expressed in the testis of both mouse and man. The amino acid differences specific to these variants are thought to function primarily in two different ways. Some substitutions result in changes in residues subject to posttranslational modification, creating new binding sites for chromatin readers. Other substitutions appear to alter the affinity of these variant histones for DNA. Decreases in affinity for DNA by histone variants can result in increases in DNA sequence accessibility, allowing previously repressed regions to become transcriptionally active. Analysis of mouse mutants of several histone variants revealed that these proteins are essential for several different phases of male germ cell development. A particularly important variant histone of the H3 family, known as H3.3, is expressed in all cell types. Unlike canonical histones, which are only synthesized and loaded onto chromatin during DNA synthesis, H3.3 (in addition to some other variants of different histone families) is produced throughout the cell cycle and its loading into chromatin is also not limited to S phase (Szenker et al., 2011). This variant is expressed at high levels throughout all stages of spermatogenesis, and mutations in H3.3-encoding genes have been found to disrupt male fertility in a variety of ways (Tang et al., 2015; Yuen et al., 2014).

Chromatin Composition and Structure in Premeiotic Spermatogonial Germ Cells

In mammals, germ cells are specified from a specific population of multipotent embryonic cells. These cells possess a chromatin configuration fairly similar to that of somatic cells, a state which is thought to remain largely unchanged throughout embryonic development. At birth a population of cells present in the testis will serve as adult spermatogonial stem cells to produce sperm throughout the life of the animal. These cells will first be induced to differentiate at puberty. As in somatic cells, different classes of chromatin modifying enzymes, catalyzing tri-methylation of histone H3 at lysine 4 (H3K4me3) and of histone H3 at lysine 27 (H3K27me3), are required for proper regulation of transcriptional activity or repression in spermatogonial stem cells and their survival (Glaser et al., 2009; Mu et al., 2014).

Spermatogonial differentiation involves a defined number of cell divisions, which serve to amplify the population of male germ cells that can become mature spermatozoa (see Fig. 2). It has been clear for many years that cellular differentiation of premeiotic spermatogonia in both humans and mice correlates with changes in chromatin configuration. Classical staining techniques to visualize chromatin packaging within the nucleus reveal an increase in the amount of compacted DNA within the nuclei of more differentiated spermatogonia. The quantity of these densely stained regions, known as heterochromatin, also increases during somatic differentiation. Heterochromatin is generally associated with regions of the genome showing low transcriptional activity, including many repetitive sequences. These transcriptionally repressed regions harbor modifications to their histones and DNA important for preventing inappropriate transcription. In male germ cells, loss of transcriptional repressive pathways including those mediating tri-methylation of lysine 9 of histone H3 (H3K9me3) or methylation of cytosines within the DNA lead to upregulation of endogenous retroviruses, some of which possess the capacity to move around the genome, potentially leading to deleterious mutations (Zamudio and Bourc’his, 2010). In order to prevent these elements from activating during spermatogenesis, a special small RNA-mediated pathway, known as the piRNA pathway, has evolved to work in concert with chromatin modifications. Together these pathways serve to safeguard the germline from acquisition of large numbers of mutations due to transposon activity.

Induction of differentiation in spermatogonial stem cells is also associated with expression of a variant form of histone H3 known as H3t. This variant, which is found in mammals, is restricted in its expression to testicular germ cells and carries several

Fig. 2 Major changes in chromatin states occurring during postnatal spermatogenesis. Timing of major events resulting in changes in chromatin structure and state during spermatogenesis are indicated in colored boxes. See text for details of each event.

amino acid substitutions relative to canonical histone H3, some of which are conserved within mammals. Biochemical analysis of the human H3T protein suggest that this variant forms nucleosomes that exhibit decreased affinity for DNA (Tachiwana et al., 2010). In addition human H3T has been found to interact preferentially with certain chromatin associated proteins. Mouse mutants for H3t are viable, but males exhibit infertility (Ueda et al., 2017). However, how the amino acid substitutions and/or regulation of this histone variant result in successful spermatogenesis remains unknown.

Chromatin Composition and Structure in Meiotic Male Germ Cells

Following their mitotic divisions, male germ cells initiate the specialized cell division process known as meiosis. Meiosis serves to randomly distribute homologous chromosomes from different parental origins in haploid descendent cells, called spermatids. This is accomplished by performing DNA replication followed by two subsequent cell divisions. A characteristic of mammalian male meiosis is a protracted period in prophase of the first meiotic division. This extended period occurs following the final DNA replication step in the male germline, meaning that changes to chromatin occurring during meiosis cannot rely upon canonical histone proteins, which normally incorporate during DNA replication. Therefore, increasing quantities of DNA replication independent variant histones, such as H3.3, become deposited into chromatin with time during meiosis.

A key feature of meiosis in all eukaryotes is the process of homologous recombination. During this process programmed double strand breaks in the DNA are formed, which are then repaired using homologous sequences on chromosomes of different parental origin as templates. This process results in the physical linkage of parental homologs together, a process necessary for appropriate homolog segregation during the first meiotic division. The chromatin surrounding meiotic double strand breaks acquires a phosphorylation of an H2A variant known as H2AX. This modification, known as γ H2AX, spreads from the site of the double strand break into the surrounding chromatin serving to recruit essential DNA repair pathway proteins.

Interestingly, the location of the double strand breaks formed during meiosis is not random, but instead occurs preferentially at so-called “hotspots.” These hotspots have been shown to be located at specific DNA sequence motifs that also exhibit important chromatin features. The Prdm9 enzyme, which can catalyze H3K4me3 and H3K36me3, has been found to recognize the sequences of these hotspots and both H3K4me3 and H3K36me3 levels have been found to be increased in such sequences (Baudat et al., 2013). These histone modifications are normally associated with transcription start sites of active genes and gene bodies of active genes respectively. This therefore represents a potential germline specific alteration of the transcription associated histone code found in somatic cells. Whether other histone modifications are also associated with hotspots and what the exact role that such histone modifications play during the process of recombination is still unclear.

During prophase, following DNA double strand break formation autosomes undergo the process of synapsis in which homologous chromosomes are linked together by structural meiotic proteins. Failure of synapsis of autosomal chromosome regions leads to a general phenomenon known as meiotic silencing of unsynapsed chromatin (MSUC), in which genes located in these regions become transcriptionally silenced (Turner, 2015). Such transcriptional silencing is associated with wholesale changes in chromatin composition and modification states, and if not resolved is frequently associated with cell death and male infertility. One feature of these unsynapsed chromosomal regions is the maintenance of γ H2AX on their chromatin, well after other synapsed regions have de-phosphorylated this site following repair of double strand breaks.

One interesting feature of mammalian recombination occurs on the sex chromosomes. Because the X and Y chromosomes in mammals exhibit significant sequence divergence, they lack an effective homolog with which to pair and to be used as a template for DNA repair. This results in their global transcriptional silencing during prophase. To compensate for loss of expression of genes located on the X chromosome, additional paralogous gene copies have evolved on autosomal chromosomes. Similar to the process of MSUC, the transcriptionally silent sex chromosomes display enrichment for γ H2AX throughout much of meiotic prophase (Turner, 2015). In addition, they also undergo a global histone replacement process in which canonical nucleosomes become depleted and replaced with nucleosomes containing H3.3 (van der Heijden et al., 2007). Following this global transition, the new H3.3 containing nucleosomes become specifically enriched for a histone modifications associated with transcriptional silencing. What role the global replacement of nucleosomes on transcriptionally silenced sex chromosomes plays in transcriptional regulation of these cells during and after meiosis remains unknown.

At endogenous retroviral sequences, DNA methylation and di-methylation of H3K9 (H3K9me2) protect against transcriptional activation and acquisition of a chromatin state permissive for meiotic double strand break formation and repair. At pericentromeric heterochromatin regions, H3K9me2 and H3K9me3 as well as associated heterochromatin proteins prevent the underlying major satellite sequences, localized on autosomes and the X chromosome, from becoming engaged in illegitimate interactions between nonhomologous chromosomes, thereby ensuring synapsis of such sequences only at homologous chromosomes and safeguarding male fertility (Peters et al., 2001).

Chromatin Composition and Structure in Postmeiotic Male Germ Cells

Postmeiotic male germ cells, called spermatids, contain a chromatin consisting of a large quantity of variant histone proteins, inherited from their meiotic predecessors. Immediately following meiosis, these cells remain in a relatively standard, transcriptionally active chromatin state. The sex chromosomes in these cells also remain largely in a configuration similar to that of

spermatocytes, enriched globally for histone modifications associated with transcriptional repression. A small number of sex-linked genes, however, become expressed following meiosis and are thought to play important roles in completion of spermatogenesis. Many of these genes are present in multiple copy arrays on the sex chromosomes (Namekawa et al., 2006). How these genes become transcriptionally activated in spermatids and whether their multicopy nature is important for this activation is not clear.

After a relatively extended initial phase, spermatids initiate final changes to their chromatin that enable their function as mature spermatozoa. One of the first dramatic changes to chromatin to occur during spermatid differentiation is a global increase in the level of histone lysine acetylation. Acetylation of lysine residues on histones neutralizes positive charges found in the histones, decreasing their affinity for negatively charged DNA. This process in male germ cells may play three different roles. First, histone acetylation may increase the accessibility of DNA on a global scale. Second, histone acetylation may serve to recruit chromatin reader proteins required for further differentiation of spermatids. Indeed mutation of a testis specific histone acetylation reader protein (Brdt) has been shown to disrupt spermatogenesis (Berkowits and Wolgemuth, 2013). Finally, acetylated histones are targets for a spermatogenic-specific proteasome complex, which can lead to the degradation of histone proteins during spermatid differentiation (Qian et al., 2013). This change in histone lysine acetylation again reflects potential differences in the germline histone code relative to that of somatic cells. In somatic cells increased histone lysine acetylation is associated with increased transcriptional activity, while in spermatids the timing of the increase in acetylation is associated with a global downregulation of transcription. How this downregulation in the presence of high levels of histone lysine acetylation is controlled at the chromatin level is still unknown.

Following the global acetylation of histones in spermatids, a uniquely spermatogenic alteration of chromatin occurs. Histone proteins are removed from chromatin and replaced with other small spermatogenesis-specific basic proteins. While exact sequences for these proteins show divergence throughout metazoans, diverse species of animals use a similar strategy to produce their spermatozoa. In mammals, initially a class of proteins known as transition proteins become incorporated into chromatin, and are then themselves evicted to be replaced by another class of proteins, known as protamines. This dramatic alteration in chromatin composition results in a greatly reduced nuclear volume. It is hypothesized that this decrease in nuclear volume results in an increased capacity for spermatozoa to swim through the female reproductive tract. Further, protamine-packaged DNA has been shown to be more resistant to DNA damaging agents than histone-packaged DNA, suggesting that histone to protamine exchange may also serve a function in protecting the genetic material during its transit to the oocyte.

As previously mentioned, meiotic, and early postmeiotic differentiation during spermatogenesis involves the incorporation of increasing quantities of variant histone proteins. These variants are produced in a DNA replication-independent manner. Interestingly, mutations in several of these variants suggest that possessing variant histone-containing chromatin is essential for the efficient transition from nucleosomal chromatin to protamine-containing chromatin. Mutations in the previously mentioned H3 variant H3.3 has been shown to result in a block in differentiation in early postmeiotic germ cells, just at the onset of histone eviction (Tang et al., 2015). Likewise, a variant of H2B (TH2B, which is expressed exclusively in male and female germ cells) is also required to enable proper nuclear condensation and protamine incorporation in spermatids (Montellier et al., 2013). An H2A variant, H2A.L.2, has also been shown to load onto chromatin prior to transition proteins (Barral et al., 2017). This loading was found to be essential for subsequent transition protein loading onto chromatin. These results suggest that rather than a two-step transition from histone to transition protein to protamine, various substeps involving variant histone incorporation prior to and in parallel with transition protein incorporation may occur in this process. The specific molecular details of the roles of these variants in the removal and subsequent replacement of histones by protamines are a subject of active investigation by many researchers.

Mutations in the protamine genes, in both mouse and human, are associated with male infertility. Indeed in mice mutations in protamine genes have been shown to be haplo-insufficient for male fertility (Cho et al., 2001). Additionally, germ cells from some human patients exhibiting spermatogenic failure are enriched for histone proteins relative to normal functional spermatozoa. Testing of human samples in infertility clinics now routinely involves use of DNA intercalating dyes, which query spermatozoa as to their nuclear compaction. Decreased nuclear compaction, a proxy for increased histone retention, indicates a decreased functional capacity for this material for in vitro fertilization. Whether retention of histone proteins is actually causative for human spermatogenic failure and infertility, however, remains unknown.

Chromatin Composition and Function of Mature Spermatozoa

Early studies of mature spermatozoa from a variety of species suggested the possibility that some histone proteins might be retained in mature sperm. More recent data analyzing several different species suggest indeed that histone to protamine exchange is not fully complete in mammals (Brykczynska et al., 2010). A small percentage of nucleosomes, the number of which appears to be species specific, are retained within the chromatin of mature spermatozoa. These nucleosomes were shown to carry posttranslational modifications found normally within active and repressed gene promoters. Identification of the sequences to which these nucleosomes bind showed an enrichment for regulatory regions of “housekeeping” genes and of genes driving developmental fate processes. These regulatory regions contain high levels of the dinucleotide CpG, in its non-DNA methylated state (Erkek et al., 2013). Between species, the fraction of retained nucleosomes in CpG-rich sequences is inversely correlated with the percentage of total retained nucleosomes in spermatozoa. Species such as mouse, which retain very few nucleosomes, show prominent retention of nucleosomes in CpG-rich regions, while humans, which retain more nucleosomes in spermatozoa, harbor nucleosomes in both CpG-rich regions and other genomic loci. It remains unclear whether the presence of nucleosomes and their associated modifications

in mature spermatozoa play a regulatory role in the establishment of transcription or in the organization of the paternal genome in subsequent generations. Protamine proteins are rapidly removed from paternal DNA after fertilization, but it is not clear whether this is also the fate of sperm-derived histone proteins.

Several experiments have suggested that increased nucleosome content on paternally inherited chromosomes may impair development of embryos. Genetic and chemical approaches that effect the level of a particular chemical modification (known as poly(ADP)-ribosylation) found on many proteins (including histones) were shown to increase nucleosome retention in mouse spermatozoa (Ihara et al., 2014). Embryos fathered by such sperm were then found to develop less successfully than those fathered by unaltered sperm. Whether this failure in development is directly induced by nucleosome retention, and not by some other effect of the method, however, has not been definitely shown.

Nucleosome-containing paternal chromosomes are also present in embryos produced by the assisted reproduction technique known as ROSI (round spermatid injection). This technique, used experimentally in animal models, is also occasionally utilized in human assisted reproductive clinics when a male patient lacks differentiated condensed haploid cells in his testes. Round spermatids from a testis biopsy are then isolated and injected into oocytes in vitro that, following oocyte activation, can develop into embryos. While this technique can give rise to full-term offspring in humans, it is still considered an experimental procedure and is not standard in most infertility clinics. This is because the success rate for ROSI is substantially lower relative to techniques using more differentiated male germ cell types (such as ICSI—intracytoplasmic sperm injection). Whether the decreased rate of success for ROSI relative to these other techniques is caused by the presence of high levels of histone containing chromatin or by some other unknown differences between spermatid and spermatozoa affecting gene regulation, genome stability and/or embryonic fitness remains to be resolved.

Regulation of Spermatogenesis by Noncoding RNAs

Wei Yan, University of Nevada, Reno School of Medicine, Reno, NV, United States

Introduction

Spermatogenesis refers to the process through which the male gamete, or sperm, are produced. Spermatogenesis occurs inside the seminiferous tubules of the testis, and involves spermatogonial proliferation (mitotic phase) followed by meiotic division of spermatocytes (meiotic phase) and differentiation of round spermatids into elongating, elongated and eventually spermatozoa (haploid phase, also called spermiogenesis) (Hermo et al., 2010). It takes several weeks for a spermatogonial stem cell to go through all three phases and ultimately differentiate into numerous spermatozoa (Hermo et al., 2010). The fully developed testicular spermatozoa are then released from the seminiferous epithelia through a process called spermiation, and the released testicular spermatozoa are further transported to rete testis and then transit through the male reproductive tract for further maturation (Sofikitis et al., 2008). Given such a complex biological process, spermatogenesis requires precise regulation of spatiotemporal expression of numerous genes, which occur at both transcriptional and post-transcriptional levels (Eddy, 1998). Genetic networks that control spermatogenesis have been partially dissected over the past two decades, and thousands of protein-coding genes have been identified to be essential for each of the three phases of spermatogenesis (Matzuk and Lamb, 2008). In addition to protein-coding genes, non-protein coding genes, which are transcribed as noncoding RNAs (ncRNAs), have also been found to play critical roles in the regulation of spermatogenesis (Holt et al., 2016). In addition to long noncoding RNAs (> 200 nt, lncRNAs) (Luk et al., 2014), a large number of small ncRNAs (sncRNAs) have been identified to be abundantly expressed in the testis, including microRNAs (miRNAs) (Ro et al., 2007), piwi-interacting RNAs (piRNAs) (Bortvin, 2013), endogenous small interference RNAs (endo-siRNAs) (Song et al., 2011), mitochondrial genome-encoded small RNAs (mitosRNAs) (Ro et al., 2013), tRNA-derived small RNAs (tsRNAs) (Peng et al., 2012), small nucleolar RNAs (snoRNAs) (Ortoger et al., 2013), etc. These sncRNAs were identified through the next-gen deep sequencing technologies. In general, these sncRNAs act jointly to fine-tune the expression of protein-coding genes at both transcriptional and post-transcriptional levels. Except for miRNAs and piRNAs, the biogenesis and physiological roles of other sncRNAs are largely unknown. Therefore, the discussion below is confined to the roles of lncRNAs, miRNAs, endo-siRNAs, and piRNAs in the regulation of spermatogenesis.

Roles of Testicular ncRNAs in Spermatogenesis

lncRNAs. Using either microarray and deep sequencing technologies, thousands of lncRNAs have been identified in both spermatogenic cells and testicular somatic cell types (Sun et al., 2013; Bao et al., 2013). lncRNAs can be divided into five subtypes based on their proximity to mRNA genes, including sense, antisense, bidirectional, intronic, and intergenic. The majority of lncRNAs are nuclear and low in abundance. lncRNAs have been shown to play critical roles in chromatin remodeling by recruiting chromatin-remodeling complexes to specific loci, which, in turn, mediate epigenetic modifications, for example, XIST, HOTAIR and H19 (Mercer and Mattick, 2013). Some lncRNAs, including promoter-associated RNAs (PARs), enhancer RNAs (eRNAs), and transcripts from ultra-conserved regions (T-UCRs), have also been found to regulate transcription through interacting with transcription factors (Mercer and Mattick, 2013; Lee, 2012). However, these putative functions were mostly established based on in vitro experiments and functions of individual lncRNAs in spermatogenesis remains to be demonstrated.

miRNAs. miRNAs were the first sncRNA species identified to be highly expressed in the testis (Ro et al., 2007). miRNAs are 22 nt in length and miRNA biogenesis starts with transcription of miRNA genes by the same transcriptional machinery used for mRNA synthesis. The miRNA-containing region of the primary miRNAs possesses unique sequences which can fold into a stem-loop/hairpin structure (Voinnet, 2009). DROSHA, a nuclear RNase III enzyme, recognizes the stem-loop and cleaves it out. The hairpin-shaped precursor miRNAs are then shipped out of the nucleus and reach the cytoplasm by exportin 5, where a cytoplasmic RNase III called Dicer dices out the two mature miRNAs from the stem region of the hairpin (Voinnet, 2009). Mature miRNAs then bind RNA-induced silencing complex (RISC) and lead the RISC to their target sites, 3'UTRs of protein coding genes. miRNAs bind to the sites in the 3'UTRs by complementary annealing using the "seed sequence" (the 2nd–7th nt) (Friedman et al., 2009). The net effects of miRNA-RISC binding to the 3'UTRs of protein coding mRNAs include translational inhibition, and stabilization/destabilization of mRNAs depending on the proximity of their binding sites to the stop codon within the 3'UTRs (Voinnet, 2009; Zhang et al., 2017). Hundreds of miRNAs are expressed in the testis and many display cell specificity; for example, many X-linked miRNAs are exclusively expressed in spermatogenic cells (Ro et al., 2007; Song et al., 2009). Ablation of *Drosha* and *Dicer* in either Sertoli cells or spermatogenic cells leads to male infertility due to severely disrupted spermatogenesis, highlighting the necessity of miRNA production in spermatogenesis (Wu et al., 2012; Papaioannou et al., 2009). However, knockout of single miRNAs seldom generates significant disruptions in spermatogenesis. This is most likely due to the fact that one miRNA can target multiple mRNAs and the 3'UTR of a particular mRNA tends to harbor binding sites for multiple miRNAs. This "one-to-multi" relationship constitutes interwoven networks among miRNAs and their targets. Thus, lack of one miRNA may not be able to generate significant effects sufficient to disrupt the function of their target mRNAs. When miRNAs that belong to the same family (i.e., share the same seed sequence) or target genes of the same pathways are inactivated simultaneously, phenotypes in particular developmental or physiological processes often show up, suggesting that miRNAs tend to function in a redundant manner (Wu et al., 2014). This phenomenon

may represent a “fail-safe” mechanism, and it is also consistent with the fine-tuning role of miRNAs in the post-transcriptional regulation of gene expression.

endo-siRNAs. Chemically synthesized small interference RNAs (siRNAs) have been used to knock down mRNAs for over two decades. But endogenous siRNAs were not believed to exist because their production requires double-stranded RNAs (dsRNAs) as substrates, which, in theory, are non-existent in healthy cells due to interferon/OAS/RNase L-mediated interferon response (Lamontagne et al., 2001). However, endo-siRNAs were first discovered in developing oocytes and early embryos, and later in spermatogenic cells (Svoboda and Flemr, 2010). Endo-siRNAs are 22 nt sncRNAs processed from endogenous dsRNAs by cytoplasmic DICER. The endogenous dsRNAs are likely transiently formed by regional annealing between the same or different transcripts (Sontheimer and Carthew, 2005). Dicer recognizes dsRNAs and cleaves them into siRNAs, which can induce rapid and efficient degradation of their host and target transcripts. Comparative studies on the phenotypic differences in *Dicer* and *Drosha* male germ cell-specific knockout mice have demonstrated that endo-siRNAs is indeed critical for normal spermatogenesis (Wu et al., 2012). However, the precise function of individual endo-siRNAs in specific time points and spermatogenic cell types during spermatogenesis remain unknown. Given the potency of siRNA-mediated mRNA decay, these endo-siRNAs are likely act when rapid degradation of certain transcripts becomes necessary during spermatogenesis.

piRNAs. piRNAs were first identified as 24–30 nt sncRNAs that bind PIWI family proteins (Luteijn and Ketting, 2013). In mice, two types of piRNAs are expressed in the testis: one expressed predominantly in spermatocytes and spermatids in adult testes, and the other abundant only in primordial germ cells (PGCs) and pro-spermatogonia in fetal testes (Bortvin, 2013). Fetal testicular piRNAs are mainly processed by the piRNA processing machinery involving MIWI2, MILI, Mael, MitoPLD and other unknown factors using the transcripts from repetitive elements as substrates (Bortvin, 2013). The massive transcriptional activation of retrotransposons, for example, LINE1, is caused by the global reprogramming events, characterized by rapid genome-wide DNA demethylation and re-methylation in PGCs between E13.5 and E15.5 in mice. By producing repetitive sequence-derived piRNAs, transcripts synthesized from the repetitive sequences including retrotransposons, can be degraded through the RNAi pathway; more importantly, these piRNAs are required for re-methylation of repetitive sequences during the establishment of the germline-specific epigenome (Bortvin, 2013). Therefore, these piRNAs appear to be able to lead to methylation of repetitive sequences from which they are derived. However, it remains unknown how piRNAs achieve this at molecular levels. The adult testicular piRNAs are abundantly expressed in meiotic and haploid male germ cells, especially in pachytene spermatocytes and round spermatids. Recent data suggest that these piRNAs are mainly transcribed from several large clusters in the genome and appear to be able to induce degradation of many transcripts expressed in haploid male germ cells, that is, spermatids (Gou et al., 2014, 2015). Given that quick turnover is critical for spermiogenesis, these piRNAs have been assigned a role in inducing massive degradation of haploid transcripts. However, given that the quick turnover of haploid transcripts occurs in an orderly manner at precise time points, how these piRNAs select specific transcripts and the identify of these piRNA targets need to be elucidated in future studies.

Epigenetic Programming of Paternally Imprinted Genes During Spermatogenesis

Stella K Hur and Marisa S Bartolomei, University of Pennsylvania, Philadelphia, PA, United States

© 2018 Elsevier Inc. All rights reserved.

Mammals are diploid, having a set of chromosomes derived from their mothers through oocytes and a set of chromosomes from their fathers through sperm. Most genes in the genome are expressed or repressed from both parental chromosomes (i.e., alleles). However, a small number of genes, termed imprinted genes, deviate from this norm. Genes that undergo the process of genomic imprinting are expressed from a single parental allele, either the maternal or the paternal allele. Genomic imprinting, including the genes that are imprinted and defined regulatory mechanisms, is well-conserved among mammals. The significance of genomic imprinting in mammalian development was formally demonstrated by nuclear transplantation experiments in the 1980s. The experiments revealed that uniparental embryos are not viable—diploid androgenetic embryos derived from two male pronuclei or diploid gynogenetic embryos derived from two female pronuclei failed to develop (McGrath and Solter, 1984; Surani et al., 1984). These results suggested that developmental failure must be due to absence or overexpression of genes that are expressed solely from one of the parental genomes, and thus normal development requires both a maternal and a paternal pronuclear contribution to the zygote. This was the first suggestion that the mammalian genome contained imprinted genes.

Approximately 200 imprinted genes have been identified in mouse, the mammal in which most experimentation has been conducted. Notably, most of the lessons learned about imprinting and imprinted genes are conserved in humans as well as other mammals that have been examined. Imprinted genes are typically located in clusters of 3–12 genes that are spread over a few Mb of DNA, although examples of single imprinted genes have been identified (Barlow and Bartolomei, 2014). The clusters harbor maternally- and paternally-expressed imprinted genes that encode both protein-coding and long noncoding (lnc) RNAs. Each well-studied cluster has a discrete imprinting control region (ICR) that governs imprinted expression and exhibits parent-of-origin-specific epigenetic marks such as DNA methylation and posttranslational histone modifications that are present throughout life (Fig. 1). For an element to be called an ICR, a functional role must be demonstrated. This is typically shown by deleting the ICR which then results in the loss of imprinting of genes in the cluster. Thus, while there are other sequences in and around imprinted genes that contain parental-specific epigenetic modifications, they cannot be claimed as ICRs unless they fulfill the criteria of (1) harboring parental-specific epigenetic marks acquired in the germline, (2) maintaining the marks throughout life, and (3) functioning to maintain imprinted gene expression. In addition to conferring parental-origin of the allele, sequences that constitute the ICRs have other roles, two of which will be briefly described here (Fig. 2). First, for many clusters including the *Igf2r/Airn*, *Cdkn1c/Kcnq1ot1*, and *Snrpn* clusters, ICRs contain the promoter for lncRNAs, which are over 100 kb in length. When transcribed, these parental allele-specific lncRNAs repress the expression of linked protein-coding genes, either by attracting repressive chromatin or transcriptionally interfering at the promoters (Latos et al., 2012). The second function of ICRs is that of an allele-specific CCCTC-binding factor (CTCF)-binding enhancer blocker. This function has been largely elucidated in studies of the *H19/Igf2* imprinted locus (Bartolomei, 2009). At this locus, *H19* and *Igf2* share enhancers and depend on the ICR to regulate which gene accesses these enhancers. On the maternal allele, the unmethylated ICR binds CTCF and blocks access of *Igf2* to enhancers, enabling *H19*

Fig. 1 Majority of the genes in the mammalian genome are expressed/repressed from both parental alleles (purple/gray boxes, respectively). However, imprinted genes (red and blue boxes) are expressed exclusively from either the maternal allele (♀) or the paternal allele (♂). Imprinted genes typically exist in clusters, and a *cis*-acting regulatory element called the imprinting control region (ICR, yellow box) coordinately regulates the expression of the imprinted genes within a cluster. One hallmark characteristic of ICRs is differential modification on each parental allele by various epigenetic modifications, such as DNA methylation at CpG dinucleotides (filled lollipops).

Fig. 2 Two main models for imprinted gene expression have been described (see text for details). In the insulator model, insulator proteins such as CTCF bind to ICR in a DNA-methylation sensitive manner, so an allele-specific insulation is achieved. In the lncRNA model, a lncRNA is transcribed from the unmethylated ICR, and silences genes *in cis* by forming a sense–antisense overlap or by affecting recruitment of transcriptional or epigenetic regulators. As a consequence, on the allele where ICR is methylated and the lncRNA is not expressed, the imprinted genes within the domain are expressed.

expression. In contrast, the ICR and *H19* are methylated on the paternal allele, which blocks CTCF binding at the ICR and enables *Igf2* to engage the shared enhancers.

As mentioned above, the parental-specific epigenetic marks at the ICRs (also referred to as “imprints”) are essential for the appropriate parent-of-origin expression of the linked imprinted genes. Therefore, proper regulation of the ICR is the key to genomic imprinting. Remarkably, ICRs (that are only a few kb in length and bare no obvious distinguishing sequence feature) are specifically modified in the germline when the two parental genomes are separated and can be distinguished. Moreover, ICRs escape the genome-wide epigenetic reprogramming that occurs after fertilization. Such escape is essential for imprinted genes to maintain their parental identity throughout the life of the organism. The focus of this article will be to describe the reprogramming that occurs in the male germline that results in parental-allele-specific marking of ICRs. Although most ICRs are marked in the maternal germline by DNA methylation during oocyte growth, there are a few well studied examples of ICRs that are epigenetically marked in the male germline.

Lifecycle of Epigenetic Programming

Imprinted genes undergo a cycle of erasure and establishment of epigenetic marks during development (Fig. 3). In mammals, the germline is recruited from somatic cells based on location in the postimplantation embryo. These somatic cells start forming the germline by repressing the somatic expression pattern and activating the germline expression pattern (Tang et al., 2016). These cells, which are destined to be reprogrammed and differentiated into mature gametes, have both maternal and paternal imprints inherited from the egg and sperm at fertilization, respectively. Following the initial specification of these so called primordial germ cells (PGCs), the cells divide and migrate along a well-defined pathway, which is accompanied by largescale erasure of the somatic epigenetic signatures of most of the genome. At this time, imprints are also erased, through both active and passive mechanisms (see below). Subsequently, reacquisition of sex-specific imprints at ICRs occurs in the germline to reflect the parental origin of the gamete as described below. ICRs are fully marked with their parental origin in the mature gametes and largely maintain this epigenetic marking despite the global epigenetic reprogramming that occurs after fertilization in the preimplantation embryo.

DNA Methylation as the Epigenetic Mark

The first identified imprinted genes in 1991 enabled investigators to assess how parental alleles were marked so that appropriate allelic expression patterns were achieved during development. The first and most easily testable candidate was DNA methylation, a modification that covalently adds a methyl group to the 5th carbon position in the cytosine residue predominantly in a CpG dinucleotide context. This modification is typically associated with gene repression either through interactions with repressive chromatin machinery or by blocking DNA access of factors that bind directly to the DNA sequence. DNA methylation is established through the action of de novo methyltransferases (DNMT3A and DNMT3B) together with their partner DNMT3L. DNA methylation is maintained during each cell division *in situ* by the action of the maintenance methyltransferase DNMT1 (which recognizes

Fig. 3 The differential ICR methylation is established during gametogenesis according to the sex of the germ cells. Depicted here is an example of paternally methylated ICR (yellow box), which is methylated only in sperm (filled lollipops represent methylated CpGs; empty lollipops represent unmethylated CpGs). Following fertilization, the parental-allele specific ICR methylation is stably maintained in the somatic cells. In the PGCs of growing embryos, however, the existing somatic imprinting marks are erased, to allow for reestablishment of a sperm- or oocyte-specific methylation at the ICR. It should also be noted that post-translational histone modification marks at ICRs are reprogrammed during development.

hemi-methylated CpG dyads and methylates the unmethylated CpG) and its functional partner UHRF1 (Li and Zhang, 2014). Thus, ICR methylation patterns that are set up in the germline or early embryo can be stably maintained.

Despite the remarkable stability of DNA methylation, there are times when DNA methylation is necessarily erased. This includes periods of genome reprogramming that occur in the germline and after fertilization or when a regulatory element that drives a specific expression state or nuclear architecture requires activation. DNA methylation can be reversed either through passive or active mechanisms. Reversal occurs passively when functional DNA methylation machinery is lacking. In this case, downregulation or cytoplasmic localization of DNMTs and the cofactor UHRF1 prevents reestablishment of DNA methylation patterns after replication, eventually resulting in dilution of 5-methylcytosine. Alternatively, erasure of DNA methylation can occur actively through the Ten–eleven translocation (TET) family of proteins (TET1, TET2, and TET3). These proteins mediate the iterative oxidation of 5-methylcytosine to 5-hydroxymethylcytosine, 5-formylcytosine, and 5-carboxylcytosine (Wu and Zhang, 2017). The oxidized forms of 5-methylcytosine can either be diluted through replication or removed through various DNA repair pathways. Although still not completely resolved, base excision repair of 5-formylcytosine and 5-carboxylcytosine by thymine DNA glycosylase (TDG) has gained the most support in the removal of these oxidized forms of cytosine and replacement with unmodified cytosine.

To summarize, based on the properties above, the methylcytosine modification fulfills the criteria for a parental identity mark or “imprint” because: (1) it can be established in either the sperm or oocyte by de novo DNA methyltransferases, (2) it can be stably propagated at each embryonic cell division by a maintenance DNA methyltransferase, and (3) it can be erased in the germline to reset the imprint in the next generation, either by a passive or active mechanism.

Acquisition of DNA methylation at ICRs in the germline has been well-studied in the last 20 years and will be described in more detail in the next section. Nevertheless, it still remains unclear what precise signals govern acquisition and reprogramming of these allelic imprints. Moreover, until a few years ago, it was thought that the entire genome was demethylated in PGCs at approximately the same time, providing a convenient explanation for how genomes could be reset to a “ground state” in preparation for the PGCs to differentiate into germ cells and acquire sex-specific imprints. It is now known that some DNA sequences maintain DNA methylation during this germline reprogramming. These elements include the repetitive intracisternal A-particle (IAP) elements as well as single copy sequences. The mechanisms of escape from reprogramming and maintenance of DNA methylation at these sequences are not understood. Careful epigenomic profiling of germline cells, including PGCs and immature gametes, additionally

demonstrated that DNA demethylation occurs in two main sequential stages. Initially, a global decrease in 5-methylcytosine occurs through passive demethylation. Subsequently, locus specific demethylation occurs at ICRs and some meiotic genes through both active and passive processes. Here again, it is unknown how these particular sequences are protected from the initial DNA demethylation step. It is known, however, that elimination of the delay in the second step of DNA demethylation, through *Dnmt1* perturbation in a mouse model, results in precocious germline differentiation as well as hypogonadism and infertility (Hargan-Calvopina et al., 2016). That is, enabling the entire genome to be demethylated in a premature and nonsequential manner has detrimental effects on the germline. While one could clearly conclude that premature activation of meiotic genes would impact germ cell maturation, it is also possible that aberrant regulation of imprinted gene expression through dysregulation of ICRs could also prompt defects in the germline.

Epigenetic Marking of ICRs in the Paternal Germline

As stated above, the mammalian germline is derived from somatic cells, which have maternally and paternally marked chromosomes. Thus, it is important that ICRs in the earliest PGCs first be reprogrammed to a “ground state” by removing the somatic parental imprints. Ultimately, the haploid sperm will harbor paternal-specific epigenetic marks regardless of whether the somatic genome was originally maternal or paternal in origin. Likewise, the haploid egg will harbor maternal-specific epigenetic marks regardless of the parental source of the genome. As described above, the ICRs must therefore first be stripped of their DNA methylation and other epigenetic marks. Due to our ability to study DNA methylation on small numbers of cells, DNA methylation reprogramming is best understood in the field. Thus, this section will focus on DNA methylation erasure and reestablishment at ICRs.

As described in the previous section, the DNA methylation of ICRs is erased in PGCs. Through the use of *Tet1* and *Tet2* deficient mice it has been shown that different ICRs have varying degrees of reliance on the process of active DNA demethylation (Dawlaty et al., 2013; Yamaguchi et al., 2013). Both *Tet1*^{-/-} and *Tet1*^{-/-}; *Tet2*^{-/-} mice derived from the relevant heterozygous crosses are viable and fertile, although females are subfertile. Analysis of sperm from both single and double knockout males shows that ICRs that normally exhibit maternal-specific methylation (thus should not be methylated in the male germline) do indeed exhibit some DNA methylation, suggesting that the germ cells were not fully erased and reprogrammed. Curiously, not every ICR is equally affected, suggesting that *Tet1* and *Tet2* deficiency impacts various ICRs differently. For example, *Peg3* and *Peg10* ICRs, which are highly methylated in oocytes and unmethylated in wild-type sperm, exhibit abnormally high DNA methylation in sperm of *Tet* mutant mice. In contrast, the *Snprn* ICR appears unaffected by *Tet* gene deficiency. To determine whether abnormal germ cell DNA methylation patterns could impact imprinting in the next generation, offspring were produced from single (*Tet1*^{-/-}) and double (*Tet1*^{-/-}; *Tet2*^{-/-}) mutant mice mated with wild-type mice (i.e., the gametes were *Tet* null but the offspring were heterozygous). Here again, a subset of offspring exhibited abnormal DNA methylation patterns and abnormal imprinted gene expression patterns, although allelic expression was not examined in these mice. These experiments illustrate a number of points. First, active DNA demethylation is required for appropriate ICR methylation patterns in sperm and normal imprinting in some offspring. Second, some germ cells and offspring exhibit normal DNA methylation patterns at ICRs, suggesting that other mechanisms are involved in resetting imprints, such as passive DNA demethylation. Finally, the difference between the results from single and double mutants is minor, suggesting that TET1 mediates the majority, if not all, of the observed ICR demethylation.

Following DNA demethylation in PGCs, the maternal-specific imprints are acquired in late stage oocytes after birth (Stewart et al., 2016). In mouse oocytes, over 20 maternally-methylated sequences at imprinted loci have been defined (designated as gDMRs or gametic differentially methylated sequences), although not all of these sequences have been demonstrated to function as ICRs. Maternal gDMRs are CpG rich, usually being considered as CpG islands, and located in promoters or genes. Although a discussion of DNA methylation acquisition at maternal ICRs is beyond the scope of this article, it has been postulated that transcription initiated upstream of the ICR is linked to acquisition of ICR methylation in the maternal germline (Chotalia et al., 2009).

In contrast to the large number of maternal gDMRs, only three paternally methylated ICRs that acquire methylation during spermatogenesis have been defined (Stewart et al., 2016). The three paternally methylated ICRs are located at the *Rasgrf1*, *H19/Igf2*, and *Gtl2/Dlk1* loci. In contrast to the gene proximal location of the CpG dense maternally-methylated gDMRs/ICRs, paternally methylated ICRs are intergenic and exhibit the genome average of DNA methylation. In the male germline in the mouse, de novo methylation is initiated at approximately embryonic day 13.5 in prospermatogonia that are arrested in mitosis, and the male DNA methylome is completely established prior to birth. Because male germline undergoes mitotic proliferation after birth and prior to entering meiosis, the paternal-specific ICRs must also undergo DNA methylation maintenance. The question of how methylation is established at the three paternal ICRs is poorly understood. The acquisition of DNA methylation at the *Rasgrf1* ICR is most clearly defined. Early DNA methylation in the male germline occurs at repetitive sequences through a de novo methylation pathway involving testis-specific Piwi-interacting RNAs (piRNAs) and DNMT3B. The piRNAs are derived from repetitive sequences and direct methylation to the corresponding sequences. The retrotransposon in the paternally-methylated *Rasgrf1* ICR triggers the piRNA pathway that targets methylation to the ICR (Watanabe et al., 2011). Because the other two intergenic paternal ICRs (*H19/Igf2* and *Gtl2/Dlk1*) do not harbor transposable elements, they likely use a distinct pathway. It has been suggested that other paternally-methylated sequences may be targeted by low level transcription, as transcription has been observed across relevant sequences prior to acquisition of DNA methylation through DNMT3A (Singh et al., 2013). However, because the male germline is more highly methylated and DNA methylation and transcription occur more promiscuously in the male germline compared

to the female germline, it is not at all clear if transcription is the critical step for the acquisition of DNA methylation imprints. In fact, it may be that methylation is indiscriminately established all over the paternal genome during spermatogenesis and the key to paternal ICRs is maintenance of methylation asymmetry following fertilization (Li et al., 2008).

Although most work has focused on DNA methylation, it is clearly known that the chromatin environment at ICRs must be favorable for de novo DNA methylation. For example, failure to remove histone 3, lysine 4 trimethylation at target sequences is inhibitory to the de novo DNA methyltransferases. This is the likely reason that DNA methylation is acquired on the two parental alleles in the germline at different times at some ICRs (Davis et al., 2000; Lucifero et al., 2004). Thus, the asymmetric establishment of DNA methylation at the maternal and paternal alleles strongly suggests that ICRs also harbor differential chromatin imprints.

Conclusions and Future Prospects

Germline imprinting represents an intriguing paradigm of mammalian epigenetic gene regulation in which parental alleles are differentially recognized in the germline to undergo allele-specific epigenetic modifications. These modifications are remembered throughout the life of the individual, except when preparing for the next generation. The mechanisms governing the DNA methylation marking of ICRs are well-established as are the mechanisms for maintenance of DNA methylation imprints. It is also clear that ICRs undergo passive and active demethylation during reprogramming, although the extent to which the active and passive mechanisms contribute to any given locus requires further study, including analyses in PGCs. Moreover, a role for other epigenetics mechanisms in establishment and maintenance is incompletely understood. Perhaps the least well understood aspect of the acquisition of male-specific imprints is how the sequences at the *H19/Igf2* and *Gtl2/Dlk1* are reproducibly recognized over all of the other sequences in the male germline. Given the powerful tools for analysis and manipulation of the germline in model organisms, it is anticipated these various questions will be addressed in the future.

Specification of Spermatogonial Stem Cells

Spermatogonial Stem Cells

Spermatogenesis is the process by which spermatozoa, the male gametes, are continually produced in the testis. This process takes place in the seminiferous epithelium. This epithelium consists of a series of multiple levels of cells that progress through the process of spermatogenesis by transitioning from less differentiated cells to more differentiated cells. Because this is an ongoing process that leads to the production of spermatozoa that are then released into the lumen of the seminiferous tubules, the epithelium must be continually replenished with additional spermatogenic cells. This is achieved by virtue of the presence of spermatogonial stem cells (SSCs) at the base of the seminiferous epithelium. These SSCs have the capability to divide asymmetrically (either directly or indirectly) such that they can sustain their own population via self-renewal as well as contributing new cells to the process of spermatogenesis via commitment to differentiation.

SSCs are the only cell type within the spermatogenic lineage capable of self-renewal and asymmetric division. In addition to undergoing self-renewal to sustain the SSC population, these cells can give rise to progenitor spermatogonia that are committed to enter the spermatogenic differentiation pathway. Progenitors then give rise to differentiating spermatogonia that then form spermatocytes, spermatids, and spermatozoa.

Development of Spermatogonial Stem Cells

The initial manifestation of the germ cell lineage in either males or females is the specification of primordial germ cells (PGCs) which are set aside as distinct from all other cell types (collectively known as somatic cells) in the early embryo at about the stage of gastrulation. In mammals, allocation of the PGCs occurs in the epiblast and the resulting PGCs then migrate to the developing genital ridges that will differentiate into either testes (in males) or ovaries (in females). In males, the PGCs give rise to prospermatogonia, which persist throughout the fetal and early postnatal period (in the mouse) before giving rise to spermatogonia. The SSCs represent only a small fraction of the undifferentiated spermatogonia. Other undifferentiated spermatogonia give rise directly to progenitors that, in the mouse, contribute to the unique first wave of spermatogenesis. These spermatogonia do not undergo self-renewal and so this population is exhausted very early during the male reproductive lifespan. Other undifferentiated spermatogonia undergo cell death. The initial SSCs give rise to the second and all subsequent waves of spermatogenesis by undergoing asymmetric divisions that facilitate self-renewal of the SSC population as well as contributing progenitors that continually replenish the seminiferous epithelium and the process of spermatogenesis. However, a key unanswered question is the nature of the mechanism by which a small subset of prospermatogonia give rise to the foundational SSCs while all other prospermatogonia transition into undifferentiated spermatogonia that immediately form progenitors that contribute to the first wave of spermatogenesis or that undergo cell death. The mechanism by which certain prospermatogonia become fated to form SSCs represents the initial specification of SSCs.

Specification of Spermatogonial Stem Cells

There are at least two theories regarding the mechanism responsible for specification of the foundational SSCs. The first theory holds that some sort of selection process operates at the cellular level to determine which prospermatogonia will give rise to SSCs. The nature of such a selection process is not at all well defined. It is not clear what cellular characteristics might form the basis upon which phenotypic distinctions arise among prospermatogonia and facilitate a mechanism that then identifies a specific subset to become SSCs. It is also difficult to imagine that such a mechanism would underly the critically important process of SSC specification in each individual in any sort of consistent manner. The alternate prevailing theory holds that a subset of prospermatogonia becomes predetermined to form the foundational SSCs on the basis of proactively regulated epigenetic programming that ensures that this subset of prospermatogonia and early undifferentiated spermatogonia will develop characteristics optimal to the formation and subsequent function of SSCs. Among these characteristics will be the ability to undergo self-renewal and asymmetric divisions, the ability to give rise to entire colonies of differentiating spermatogenic cells (something that can be directly assessed by a spermatogonial transplantation assay), and maintenance of advantageous characteristics such as enhanced genetic integrity.

Evidence for Predetermination of Spermatogonial Stem Cells

Recent studies appear to support the predetermination theory. Analysis of gene expression at the single cell level has clearly revealed the presence of distinct subpopulations of undifferentiated spermatogonia, and transplantation analyses have shown that one of these subpopulations possesses the majority of the capability to seed spermatogenesis in a recipient testis (= SSC function). Further

studies have shown that this same subpopulation also maintains enhanced genetic integrity relative to the other spermatogonial subtypes, and that these indications of heterogeneity can also be seen in earlier prospermatogonia.

Reproduction is central to the process of evolution, and, in the male, SSCs are critical to the process of reproduction. An attractive feature of the predetermination theory is that it invokes a proactive developmental mechanism that has the capacity to ensure that prospermatogonia bearing optimal characteristics will preferentially give rise to the foundational SSCs that will, in turn, ultimately give rise to the male gametes. This will then maximize the likelihood that optimal characteristics will be transmitted to subsequent generations, all of which will benefit the species.

Summary

The male germ line is unique in that it derives from PGCs that are allocated as germ cells very early during development, and then give rise to prospermatogonia, a subset of which then give rise to the foundational SSCs. Prior to the emergence of SSCs, none of the earlier male germ cell types has the capacity to self-renew, rather they progress via a unidirectional developmental process from PGCs to prospermatogonia and then, in the case of a small subset of prospermatogonia, to SSCs. Following the SSC stage, all subsequent spermatogenic cell types also lack the capacity to self-renew as they also progress through the unidirectional differentiation process of spermatogenesis to form spermatozoa. Thus, the SSCs are truly unique among male germ cells and are the only cells that participate in more than one wave of spermatogenesis. As such, it is critical that they develop and maintain optimal characteristics, and a predetermination mechanism of specification appears to be most consistent with this concept.

Glossary

SSC	Spermatogonial stem cell
Rhox10	Reproductive homeobox 10
A _s	A single spermatogonia
A _{pr}	A paired spermatogonia
A _a	A aligned spermatogonia
PI3K	Phosphoinositide 3-kinase
AKT	Protein kinase B (PKB)
MAP2K1	Mitogen-activated protein kinase kinase 1
Etv5	ETS Variant 5
CXCR4	C-X-C chemokine receptor 4
RAR γ	Retinoic acid receptor gamma
mTORC1	Mamalian target of rapamycin complex 1
REDD1	Regulated in development and DNA damage response 1
STAT3	Signal transducer and activator of transcription 3

Spermatogonial Stem Cell Dynamics

The majority of our understanding of SSC biology comes from rodent models; therefore, this chapter will focus on evidence from the mouse model. SSCs arise postnatally from the transient pro-spermatogonia or gonocyte population. Prospermatogonia are the only germ cells present in the neonatal testis cords until expression of the transcription factor reproductive homeobox 10 (*Rhox10*) provides the signal to differentiate and establish the SSC pool (Song et al., 2016). In an adult testes, SSCs are rare and believed to constitute only about 0.03% of all germ cells (Tegelenbosch and De Rooij, 1993). The low proportion of SSCs in the total germ cell population can support spermatogenesis through multiple mitotic amplification divisions. The number of amplification divisions differs between species which greatly influences their spermatogenic output (Hess and Renato de Franca, 2008). In a mouse testes, SSCs are a subset of A_{single} (A_s) spermatogonia, which divide to A_{paired} (A_{pr}) and then A_{aligned} (A_{al}) (4, 6, 8, 16 and rarely 32 cells) spermatogonia. A_{al} cells then differentiate to A1 spermatogonia without division, then divide to form A2, A3, A4, intermediate and type B spermatogonia before entering meiosis as a spermatocyte (De Rooij, 2001). These spermatogonia clones are all linked by intercellular bridges resulting from incomplete cytokinesis. The main hypotheses for the role of these intercellular bridges involve the ability for the cellular clone to share cytoplasmic content and facilitate synchronous cell division in the later spermatogonia clones (A1-type B spermatogonia). This becomes especially important for coordinating meiotic entry (Greenbaum et al., 2011).

It has long been thought that once A_s spermatogonia divide to become A_{pr} spermatogonia, the cells are committed to differentiation. However, more recently, a series of studies demonstrated that early progenitor cells are capable of reverting back to a stem cell phenotype (Barroca et al., 2009; Nakagawa et al., 2010; Hara et al., 2014). Through transplantation experiments, Barroca et al. (2009) found that isolated progenitor cells were able to repopulate a germ-cell-depleted testes albeit at a much lower efficiency than isolated stem cells. Through in vivo imaging studies, Nakagawa et al. (2010) established that, during steady state spermatogenesis in mouse, dividing clones up to A_{al-8} have the ability to fragment from their dividing sister cells, become an A_s spermatogonium and regain stem cell function. The rate of fragmentation was increased considerably during regeneration after toxic insult to the testes. Similar findings were previously reported in *Drosophila melanogaster* (Brawley and Matunis, 2004) which demonstrates that this phenomenon of transient amplifying progenitor cells being capable of de-differentiating is highly conserved.

Spermatogonial Stem Cell Markers

One persistent challenge in the field of SSC biology is the ability to specifically identify and isolate this cell population for study. Currently, the only conclusive way to determine if a population of cells contains stem cells is by transplanting them into a germ cell-depleted recipient animal and examine the recipient testes 2 months post transplantation for donor derived colonization and spermatogenesis. However, the dynamic nature of SSCs described above confounds this as well as other approaches to examine SSCs.

The identification of several differentially expressed proteins have helped to characterize subpopulations of spermatogonia that have increased stem cell potential (Table 1). In Shinohara et al., 1999, Shinohara et al. found that cell populations enriched

Table 1 Summary of factors involved in SSC regulation discussed in this article.

<i>Name</i>	<i>Role in SSC Biology</i>	<i>Evidence</i>
$\beta 1$ -integrin	Positive population enriched in stem cell activity	Transplantation
$\alpha 6$ -integrin	Positive population enriched in stem cell activity	Transplantation
THY-1	Positive population enriched in stem cell activity	Transplantation
ID4	SSC marker	Immunohistochemistry and transplantation
PAX7	SSC marker	Immunohistochemistry, lineage tracing and transplantation
GDNF	Required for SSC self-renewal signaling through GFR $\alpha 1$ /RET	Knock-out studies and in vitro culture system
FGF2	Important for SSC self-renewal	In vitro culture system
CSF1	Important for SSC self-renewal	Microarray studies, immunohistochemistry and in vitro culture system
CXCL12	Required for SSC maintenance signaling through CXCR4	Immunohistochemistry, in vitro culture system and knockout model studies
Retinoic acid	Pulsatile retinoic acid stimulation is required for differentiation and spermatogenesis	Vitamin A deficiency models, immunohistochemistry, knockout model studies and in vitro culture system
PLZF	Undifferentiated spermatogonia marker and required for SSC self-renewal and maintenance	Immunohistochemistry, knock-out studies, transplantation and in vitro culture system
GFR $\alpha 1$ /RET	Undifferentiated spermatogonia marker and required for SSC self-renewal	Immunohistochemistry, in vivo imaging and in vitro culture system
BCL6B	Expression required for SSC self-renewal	Microarray studies, in vitro culture system and knockout model studies
RB1	Required for SSC self-renewal and maintenance of the pool	In vitro culture system and conditional knockout studies
NANOS2	Undifferentiated spermatogonia marker, required for SSC self-renewal and maintenance	Immunohistochemistry, lineage tracing, knockout and overexpression models
Reactive oxygen species	Finite amounts required for SSC self-renewal	In vitro culture system, inhibitor/enhancer studies and transplantation studies
SALL4	Early differentiating spermatogonia marker required for SSC differentiation	Immunohistochemistry, co-immunoprecipitation, knockout studies and ChIP-seq
NGN3	Early differentiating spermatogonia marker required for SSC differentiation	Immunohistochemistry, lineage tracing experiments, transplantation and in vitro culture system
SOX3	Expression required for early spermatogonia differentiation	Immunohistochemistry and knockout model studies

for $\beta 1$ -integrin and $\alpha 6$ -integrin expressing spermatogonia have higher stem cell capacity following transplantation than non-enriched cells. Transplantation experiments using THY-1⁺ (CD90.2) spermatogonia have also established this population to be enriched in stem cell activity (Kubota et al., 2003). Glial cell line-derived neurotrophic factor receptor $\alpha 1$ (GFR $\alpha 1$) is expressed in A_s, A_{pr} and some A_{al} spermatogonia and has become a well established protein marker of the undifferentiated spermatogonia population that contains stem cells (Hofmann et al., 2005).

Recently, two other proteins, inhibitor of DNA binding 4 (ID4) and paired box transcription factor 7 (PAX7), have been introduced to the field as more specific stem cell markers (Oatley et al., 2011; Aloisio et al., 2014). ID4 expression is restricted to a subset of A_s spermatogonia and, upon transplantation of ID4 positive spermatogonia, recipient testes are extensively colonized (Oatley et al., 2011; Chan et al., 2014). PAX7 is expressed in a very rare subpopulation of A_s spermatogonia. Lineage tracing experiments found that a single PAX7 positive spermatogonium can differentiate to germ cells of all spermatogenic stages. Additionally, PAX7 positive spermatogonia are resistant to germ cell ablation by chemo- and radiotherapy and expand in number after these toxic insults (Aloisio et al., 2014). This regenerative cell behavior has been established as a stem cell hallmark in other stem cell systems.

Spermatogonial Stem Cell Niche Regulation

The specific cellular, molecular and structural environment that supports stem cell function is known as its niche. The SSC niche is located at the periphery of the seminiferous tubules along the basement membrane produced by Sertoli and peritubular myoid cells. A schematic representation of the cell associations and factors contributing to the stem cell niche in the testis is presented in Fig. 1. Time-lapse imaging experiments have also revealed that undifferentiated type A spermatogonia are over-represented along sections of the seminiferous tubules adjacent to blood vessels and migrate away from this vascular-associated niche upon differentiation (Yoshida et al., 2007).

Several niche-cell secreted ligands are important for SSC maintenance (Table 1). The best studied ligand, glial cell-line derived neurotrophic factor (GDNF), is secreted by Sertoli as well as peritubular myoid cells under testosterone pulsatile controlled release

Fig. 1 Schematic illustration of the SSC niche in the testis.

(Meng et al., 2000; Tadokoro et al., 2002; Yomogida et al., 2003; Chen et al., 2016). GDNF signals through the GFR α 1/RET tyrosine kinase receptor dimer located on undifferentiated spermatogonia to activate the PI3K-Akt pathway which promotes proliferation and self-renewal (Braydich-Stolle et al., 2007; Lee et al., 2007; Oatley et al., 2007). Another important factor for SSC self-renewal is fibroblast growth factor 2 (FGF2) which activates MAP2K1 and ultimately up-regulates *Etv5* and *Bcl6b* gene expression (Kubota et al., 2004; Ishii et al., 2012). Mouse spermatogonia in vitro culture systems require these two growth factors, GDNF and FGF2, for expansion of undifferentiated spermatogonia.

A microarray screen revealed that colony stimulating factor 1 receptor (*Csf1r*) is up-regulated on THY1⁺ compared to THY1⁻ testis cells (Oatley et al., 2009). Colony stimulating factor 1 (CSF1) ligand is secreted by both Leydig and peritubular myoid cells and promotes self-renewal of SSCs in vitro. Another ligand-receptor interaction that is important for SSC self-renewal is CXCL12 secreted by Sertoli cells and CXCR4 which is expressed on a subset of undifferentiated spermatogonia (Yang et al., 2013b). Upon inhibition of CXCR4, spermatogonia display increased propensity to differentiate in vitro upon retinoic acid (RA) stimulation (a potent inducer of differentiation) and this leads to disrupted spermatogenesis in vivo.

RA is synthesized from dietary vitamin A and RA signaling from Sertoli and other germ cells is essential for spermatogenesis (Morales and Griswold, 1987; Sugimoto et al., 2012). As GFR α 1 positive undifferentiated spermatogonia begin to differentiate, they start expressing the transcription factor neurogenin-3 (NGN3). NGN3⁺ spermatogonia express retinoic acid receptor gamma (RAR γ) and are therefore responsive to retinoic acid induced differentiation (Ikami et al., 2015).

Transcriptional Regulation of Spermatogonial Stem Cells

Our understanding of the transcriptional regulation of SSC maintenance is constantly evolving and a hot area of research. Several factors that play a key role in SSC self-renewal and differentiation have been identified (Table 1).

Self-Renewal

In 2004, the *luxoid* mutant mouse, which has a mutation in the gene encoding *Plzf*, was observed to have severe spermatogenic defects (Buaas et al., 2004; Costoya et al., 2004). PLZF is expressed in undifferentiated spermatogonia and its absence leads to progressive germ cell loss. More recently, Hobbs et al. (2010) demonstrated that PLZF decreases mammalian target of rapamycin complex 1 (mTORC1) activity, which promotes proliferation and differentiation in multiple stem cell systems, via inducing mTORC1 inhibitor regulated in development and DNA damage response 1 (REDD1). There is evidence that this regulation of mTORC1 by PLZF affects the responsiveness of undifferentiated spermatogonia to GDNF self-renewal signaling. Microarray analysis of established spermatogonia cultures grown in the presence or absence of GDNF identified expression of the transcription repressor B-cell lymphoma member 6 (*Bcl6b*) as being regulated by GDNF signaling and important for SSC self-renewal (Oatley et al., 2006). Further analysis of *Bcl6b* knock-out testes revealed degenerating tubules, devoid of spermatogenesis confirming the role of BCL6B in SSC self-renewal in vivo.

Expression of a tumor suppressor gene that encodes for retinoblastoma protein (RB) has also been shown to be important for SSC maintenance and self-renewal (Hu et al., 2013; Yang et al., 2013a). Conditional knockout studies of *Rb1* in the germline show that first wave spermatogenesis occurs followed by progressive loss of all germ cells due to failure of the GRF α 1⁺ A_s spermatogonia population to self-renew. Lineage tracing experiments demonstrated undifferentiated spermatogonia expressing RNA-binding protein NANOS2 give rise to the entire spermatogenic lineage (Sada et al., 2009). Conditional knockout and over-expression studies in vivo show that NANOS2 is required for SSC self-renewal and long-term maintenance of the pool. In addition to expression of these specific genes, the generation of finite amounts of reactive oxygen species (ROS) within SSCs was shown to be required for self-renewal in vitro (Morimoto et al., 2013). When ROS generation was inhibited in vitro, numbers of spermatogonia in cultures decreased but when ROS production is slightly elevated, SSC doubling time decreases which, in turn, increases SSC cell numbers.

Differentiation

Several transcriptional mechanisms of SSC differentiation have also been identified. Expression of the transcription factor spalt-like 4 (*Sall4*) in undifferentiated spermatogonia promotes differentiation by suppressing PLZF activity (Hobbs et al., 2012; Gassei and Orwig, 2013; Lovelace et al., 2016). PLZF promotes SSC self-renewal, in part, by suppressing gene networks required for differentiation. SALL4 removes this repression by interacting with PLZF to facilitate differentiation. Similar to the antagonist relationship of SALL4 with PLZF, increasing expression of neurogenin 3 (NGN3) in the GRF α 1⁺ undifferentiated spermatogonia population coincides with differentiation (Yoshida et al., 2004; Nakagawa et al., 2010). NGN3 expression was found to be regulated by STAT3 activation and to ultimately induce differentiation in vitro and in vivo following transplantation of *Ngn3* deficient spermatogonia (Kaucher et al., 2012). Sry-related homeobox 3 (SOX3) has also been associated with NGN3 expression and early spermatogonia differentiation (Raverot et al., 2005). Undifferentiated spermatogonia fail to differentiate in *Sox3* knockout testes resulting in tubules containing undifferentiated spermatogonia and Sertoli cells only.

Summary

In summary, regulation of SSC function to achieve a balance between self-renewal and differentiation is essential for male fertility. While several key factors and pathways active in mammalian SSCs have been elucidated, predominantly in the mouse model (summarized in Table 1 and Fig. 1), a more complete picture and translation to other non-rodent species are still under intense investigation. Translating these mouse model findings as well as elucidating novel mechanisms in human SSC regulation are important for increasing our understanding of clinical male infertility. Knowing which pathways are critical for normal SSC maintenance provides potential targets for diagnosis and ultimately treatment of male infertility.

Introduction

Spermatogenesis is complex, but well-organized, and is one of the most productive systems in mammalian tissues. Millions to hundreds of millions of spermatozoa are produced from the beginning of puberty in the male testes, and the high productivity continues until old age. Spermatogonial stem cells (SSCs) are responsible for maintaining life-long spermatogenesis and are capable of regenerating complete spermatogenesis when it is damaged by injury.

Since the 1950s using rodents, mammalian SSCs have been studied by means of histological sections, whole mounts of seminiferous tubules, and H^3 -thymidine labeling experiments for cell-kinetics. As a result, putative SSCs are identified as a small subpopulation of type A spermatogonia, namely undifferentiated spermatogonia. Undifferentiated spermatogonia are the initial stage of spermatogenesis and are subdivided into type A_{single} (A_s), A_{paired} (A_{pr}), and A_{aligned} (A_{al}) according to the number of cells connected by intercellular bridges. A_s spermatogonia have long been considered to be SSCs because A_{pr} and A_{al} spermatogonia are derived from A_s spermatogonia, and the interconnected forms are thought to be a well-conserved sign of germ cell differentiation in various species. However, these definitions were not established by the biological activity of A_s spermatogonia. Therefore, it is impossible to know whether A_s spermatogonia are indeed SSCs. Like other stem cells in the body, SSCs must be defined by their biological competence, in which single cells possess the capacity of both self-renewal and differentiation to the terminal cell type characteristic of that tissue. Spermatogonial transplantation is an experimental system that allows evaluating SSC competence in donor cell populations, and the only method to unequivocally identify SSCs based on their competency.

Spermatogonial Transplantation as a Functional Assay for SSCs

Spermatogonial Transplantation Procedure

The spermatogonial transplantation technique was developed to identify SSCs using mice in 1994 (Brinster and Avarbock, 1994; Brinster and Zimmermann, 1994). To establish the transplantation technique in the initial experiments, donor cells that express a reporter gene were directly injected into the seminiferous tubule of an infertile recipient male. Although three injection methods have been developed (Kubota and Brinster, 2017), microinjection via efferent ducts appeared to be the best for controlling the injection volume, which is important for quantitative analysis of SSCs. The recipient males were originally made infertile by injecting the alkylating chemotherapeutic agent, Busulfan. Alternatively mutant mice with deficiencies of germ cell development, such as W mutant mice (Brinster and Avarbock, 1994), can also be used as recipients to avoid chemotherapeutic treatment of the recipient. After microinjection of testicular cells into the spermatogenesis-impaired seminiferous tubules, a small subpopulation of the donor cells is able to pass through the blood-testis barrier of the Sertoli cells and colonizes the basement membrane of the tubule. The donor cells that reach the basement membrane begin to proliferate laterally, and only after 1 month donor-derived spermatocytes appear in the adluminal compartment of the seminiferous tubule. Spermatozoa can be identified in the lumen of the tubule after 2 months (Nagano et al., 1999). The reconstituted spermatogenesis continues throughout the remaining life of the recipients, and spermatozoa derived from donor cells can fertilize eggs, resulting in production of fertile progeny carrying the donor male haplotype. These characteristics of donor cells following transplantation establish SSC competence of the transplanted cells. Thus, development of the spermatogonial transplantation procedure has made it possible to unequivocally identify SSCs in any donor-cell population based on their biological function.

Quantitative Functional Assay for SSCs

The transplantation procedure can be used as a quantitative assay for retrospective identification of SSCs. When testis cells from a transgenic mouse that expresses a reporter gene, such as β -galactosidase (β -gal) or green fluorescent protein (GFP), are transplanted into infertile recipient testes, donor-derived spermatogenesis can be unequivocally identified by visualizing the reporter proteins. In recipient testes transplanted with β -gal-expressing germ cells, donor-derived spermatogenesis can be identified as blue colonies after staining with the substrate, X-gal (5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside), 2 months following transplantation (Fig. 1). These colonies are each derived from a single donor cell, and the colony number does not change from 1 to 4 months, whereas the length of colonies increases (Nagano et al., 1999). Thus, the number of blue colonies represents the number of SSCs in the donor cell population that can colonize the recipient testis. Only about 10% of SSCs in a donor cell population that is transplanted form colonies; consequently, the number of colonies is believed to represent only one tenth of the true stem cell number (Nagano, 2003).

Fig. 1 Outline of quantitative transplantation assay for SSCs. A single cell suspension prepared from testes of transgenic mice expressing a reporter gene (e.g. β -gal) by enzymatic digestion is injected into the seminiferous tubules of an infertile recipient male. Cells from in vitro culture or cells fractionated by FACS or other selection methods can be used for a donor cell population. Two months after transplantation, donor-derived spermatogenesis can be detected in the recipient testis as *blue* stretches. Because each spermatogenic colony is derived from a single SSC, the number of colonies represents the number of SSCs in the donor cell suspension. The length of the colonies demonstrates the degree of SSC expansion. Modified from Nagano, M., Avarbock, M. R. and Brinster, R. L. (1999). Defining the Identity of SSCs

Estimated SSC Number in a Testis

The number of A_s spermatogonia in the testis is very low. A whole mount analysis of seminiferous tubules indicated that only 0.03% of all germ cells in an adult mouse testis were A_s spermatogonia. Because all A_s spermatogonia may not be SSCs, the number of SSCs would be fewer than that of A_s spermatogonia. Estimation of the SSC number by the spermatogonial transplantation assay indicated that approximately 0.01% of all seminiferous tubule cells are functional SSCs and that the SSC number in an individual testis is as low as 3000 (Nagano, 2003). The rarity of SSCs in the testis makes studies of SSCs very difficult; therefore, defining the identity of SSCs is crucial to clarifying their biological and molecular characteristics.

Cell Surface Characteristics of SSCs

One of the most extensively studied characteristics of SSCs is their cell surface phenotype. Determining the cell surface characteristics of SSCs is important to enrich the rare SSC population, and the following process can be used. Initially, a single cell suspension is prepared from testes and stained with fluorochrome-conjugated antibodies against cell surface molecules. Subsequently, the stained testicular cell population is fractionated based on the expression patterns of the surface molecules, and each fraction of cells is isolated by fluorescence activated cell sorting (FACS). To determine which subpopulation of testis cells includes SSCs, isolated cell populations are subjected to the transplantation assay. Two months after transplantation of each cell fraction, recipient testes are examined to identify donor-derived spermatogenesis (Fig. 1). The number of spermatogenic colonies generated by different cell populations indicates the number of SSCs in that population of cells. By repeating this process, the cell surface phenotype of mouse SSCs has been determined to be $THY1^{lo}$ $ITGA6^{+}$ $KIT^{-/lo}$ $MHC-I^{-}$ (major histocompatibility complex class I) in mice (Kubota et al., 2003). Further characterization by flow cytometry demonstrated that mouse SSCs express several other surface molecules including GFRA1 (GDNF family receptor alpha 1), CDH1, CD9, EPCAM, MCAM, and others (Kubota and Brinster, 2017). These cell surface molecules are mainly categorized as cell adhesion molecules and growth factor receptors, some of which regulate SSC functions. Furthermore, cellular activity, such as efflux pump activity, mitochondrial activity, cell-cycle, and intracellular enzymatic activity, can be used for FACS-based cell fractionation. At present, no cell surface molecule or cellular characteristic that

exclusively identifies SSCs has been identified. Nevertheless, while the concentration of SSCs in adult testes is 1–2 in 10,000 testicular cells, that of $\text{THY1}^{\text{lo}} \text{ITGA6}^+ \text{KIT}^{-/\text{lo}} \text{MHC-I}^-$ cells in adult testes is increased to approximately 1 in 30 (Kubota et al., 2003). The SSC-enriched cell population greatly facilitates further investigation of SSC characteristics at cellular and molecular levels.

Intracellular Characteristics of SSCs

Although flow cytometry of cell surface molecules is a powerful and an effective approach to dissect the SSC phenotype, knowledge about gene expression characteristics of undifferentiated spermatogonia is increased by comparative or comprehensive gene expression analyses between SSCs and differentiating cells. Consequently, many intracellular molecules, such as transcription factors or RNA binding proteins, which are expressed exclusively in undifferentiated spermatogonia or primarily in A_s spermatogonia, have been identified. For determining whether they are SSC-specific genes, transgenic mice in which a reporter gene, such as *GFP*, is inserted downstream of the promoter of a putative SSC-specific gene, have been used. Following identification of reporter gene-expressing cells in the testes of the transgenic mice, the cells are isolated by FACS and subjected to the spermatogonial transplantation assay (Kubota and Brinster, 2017). Again, no SSC specific molecules have been identified, but this approach could allow better SSC enrichment than existing techniques relying on cell surface markers alone. Furthermore, this approach is important to delineate the ordered expression of gene expression during spermatogonial differentiation from SSCs and to determine the molecular signature of the stem cell.

Factors Influencing SSC Competence

Impact of SSC Niche

The surrounding microenvironment of stem cells is called the stem cell niche, which has been shown to influence SSC competence. When SSCs from adults were transplanted into pups and adult recipient testes, the number of spermatogenic colonies in pup testes was approximately 10 times greater than in adult testes (Shinohara et al., 2001; Fig. 2). In addition, colonies generated were four times longer in pup testes compared with those in adults (Fig. 2). These findings indicated that the SSC niche in pups is more accessible and supportive of transplanted SSCs than that in adults. Conversely, aged atrophic testes ($\sim 2+$ years) are less supportive of transplanted SSCs, and the competence of resident SSCs in those testes deteriorates (Zhang et al., 2006). Although some males can maintain spermatogenesis until old age ($\sim 2+$ years), the amount of spermatogenesis begins to decrease after the first year, which results from a decreasing number of SSCs (Zhang et al., 2006; Ryu et al., 2006). By 2 years of age, the SSC number in the atrophic testes is significantly decreased, which is clearly established by the SSC transplantation technique. Furthermore, the SSC niche in atrophic testes of 2-year-old mice appears to be deteriorated because young SSCs rarely colonized and regenerated spermatogenesis in those recipient mice following transplantation (Zhang et al., 2006). Thus, the decrease in SSC competence during aging is largely influenced by the SSC niche. To support this conclusion, serial transplantation of SSCs into young recipient males revealed that the SSC number and their competency did not change up to 32 months, during which SSCs were serially transplanted eight times, every 3 months into young recipients (Ryu et al., 2006). These serial transplantation experiments clearly indicate that the young SSC niche extends the SSC competency beyond the normal life span of the mouse.

Sertoli cells, myoid cells, Leydig cells, and potentially other interstitial cells, as well as spermatogonia make up the SSC niche. In most cases, their exact contribution is unknown; however, the number of Sertoli cells appear to have a major influence on the number of niches available for SSCs. This may result from their production of glial cell-line derived neurotrophic factor (GDNF) and fibroblast growth factor 2 (FGF2), the primary and secondary critical soluble factors (Kubota et al., 2004b). When the number of Sertoli cells in the recipient testis is increased, donor cell-derived colonies are significantly increased (Oatley et al., 2011).

Fig. 2 Developmental effect of the stem cell niche on SSC competence. Donor SSCs from adult testes were transplanted into pup or adult recipient testes. The colony number and length generated in recipient testes were analyzed 2 months after transplantation. The colony number and length in pup testes were 9.4-fold and 4-fold greater than those in adult testes, respectively (Shinohara et al., 2001). This result indicated that the SSC niche in immature testes is more accessible and supportive for transplanted SSCs.

Additionally, a supportive role of insulin-like growth factor 1 (IGF1) and colony stimulating factor 1 (CSF1) on SSC proliferation in culture has been reported (Kubota et al., 2004b; Oatley et al., 2009). Because IGF1 and CSF1 are expressed in Sertoli cells and Leydig/myoid cells, respectively, these factors likely play a role as niche factors for SSCs.

Functional Evaluation of Spermatogenic Defects

Many congenitally infertile mouse lines that are caused by spontaneous or introduced genetic mutations have been established, and spermatogonial transplantation provides a valuable approach to elucidate the mechanisms of these spermatogenic defects. If donor germ cells from an adult spermatogenesis-impaired mutant mouse are able to colonize a wild-type recipient mouse following transplantation and reconstitute donor-derived spermatogenesis, then the SSCs of the mutant infertile mice are competent. We also know in this mutant mouse that the SSC niche is intact, because the SSCs were able to survive until puberty. Therefore, the spermatogenic failure likely results from a defect in the differentiation environment. This can be confirmed by transplantation of wild-type SSCs into the testis of the spermatogenesis-impaired mutant mouse. If the differentiation environment is defective, spermatogenesis would not be reconstituted by wild-type SSCs. On the other hand, if donor germ cells from an adult mutant mouse are unable to reconstitute donor-derived spermatogenesis in a wild-type recipient mouse, the germ cells themselves likely have a defect. Again, this can be confirmed by transplantation of wild-type SSCs. If germ cells of the mutant mice are the causal factor for impaired spermatogenesis, donor wild-type SSCs would reconstitute spermatogenesis in the spermatogenesis-impaired mutant recipients. The congenital mutations of the *Steel* (*Sl*) locus (encoding KIT-ligand, KITL) and the *white-spotting* (*W*) locus (encoding c-kit receptor tyrosine kinase, KIT) are examples of the above situations (Ogawa et al., 2000). Mice with the *Sl^d* mutation (e.g. *Kitl^{Sl}/Kitl^{Sl-d}*) show no expression of the membrane-bound form of KITL on Sertoli cells and have impaired spermatogenesis (Fig. 3B). KIT is expressed

Fig. 3 Functional evaluation of congenital spermatogenic defects by spermatogonial transplantation. (A) In wild-type mice, Sertoli cells (S) express both membrane-bound KITL and soluble KITL. Spermatogonia (G) express KIT, the receptor for KITL, which interacts with both the membrane-bound and soluble forms of KITL. The membrane-bound KITL can stimulate spermatogonia more strongly than soluble KITL. Wild-type mice have no defect of these molecules and show normal spermatogenesis. (B) *Sl* mutant mice (*Kitl^{Sl}/Kitl^{Sl-d}*) have mutations in the *Sl* locus and express soluble KITL only, but not the membrane-bound KITL, by Sertoli cells. No spermatogenesis occurs in *Sl* mutant mice. (C) *W* mutant mice (*Kitl^W/Kitl^{W-v}*) have mutations in the *W* locus, and the mutant cannot transduce the stimulatory signal after binding of KITL. No spermatogenesis occurs in *W* mutant mice. When testis cells from *Sl* mutant mice are transplanted into the seminiferous tubules of *W* mutant mice, they establish spermatogenesis in the recipient *W* mutant mice, because spermatogonia of *Sl* mutant mice display the normal, wild-type KIT on immediate descendants of the SSCs, and the Sertoli cells of the *W* mutant mice express membrane-bound KITL. The recipient *W* mice are fertile and produce progeny with the *Sl* phenotype. Modified from Ogawa, T., Dobrinski, I., Avarbock, M. R. and Brinster, R. L. (2000). Transplantation of male germ line stem cells restores fertility in infertile mice. *Nature Medicine* 6, 29–34.

on differentiating spermatogonia, but its expression is negligible on undifferentiated spermatogonia in wild-type mice (Fig. 3A). Because SSCs from the Sl^d mice could reconstitute spermatogenesis after transplantation into wild-type mice that express both soluble and membrane-bound forms of KITL (Fig. 3A, $Kitl^+/Kitl^+$), it indicates that Sl^d SSCs are normal and the membrane-bound form of KITL is required for spermatogonial differentiation (Shinohara et al., 2000). Conversely, the W mutant mice have a congenital mutation of KIT (e.g. Kit^W/Kit^{W-v}) and show impaired spermatogenesis (Fig. 3C). When SSCs from wild-type mice that express KIT (Fig. 3A, Kit^+/Kit^+) were transplanted into the W mouse testes, complete spermatogenesis could be reconstituted (Brinster and Avarbock, 1994). This result indicated that the stimulatory signal via KIT on spermatogonia is crucial to complete spermatogenesis (Ogawa et al., 2000). Most notably, transplantation of SSCs from the Sl^d mutant mice into the testes of W mutant mice resulted in normal spermatogenesis and produced fertile progeny from the donor Sl^d SSCs (Ogawa et al., 2000). Using the transplantation assay between mutant and wild-type mice, the mechanisms of spermatogenic defects of a number of mutant mice have been investigated, and the functions of mutated genes are clarified. Spermatogonial transplantation is an extremely valuable method to elucidate deficiencies in the competency of SSCs including self-renewal potential and differentiation ability, their niche, or differentiation environments in infertile males.

Spermatogonial Transplantation of Non-Mouse SSCs

Application to Non-Mouse Species

Spermatogonial transplantation has now been applied to rats, goats, cattle, pigs, cats, dogs, and monkeys to study SSCs and determine their competency (Kubota and Brinster, 2017). For rats and hamsters, the procedure is identical to mouse transplantation. However, in non-rodents, the transplantation procedure and recipient preparation have been modified according to the anatomical structure of the testis. In species with a large testis and a centrally located rete testis, donor cells are generally injected using ultrasound-guided pipette placement into the rete testis, which has resulted in long-term donor-derived spermatogenesis. Furthermore, in goats and sheep, progeny have been generated by mating with females, and the donor haplotype was transmitted to subsequent generations (Herrid et al., 2009; Honaramooz et al., 2003). Therefore, spermatogonial transplantation has been shown to be applicable for identification and evaluation of SSCs of many mammalian species and has occasionally been used to assess the colonizing ability of the injected cell population. The possible limitation in studies of non-rodent SSC competency using a donor and recipient of the same species is the availability of transgenic strains, time to reach puberty, and cost for experiments in larger animals.

Xenogeneic Transplantation

An alternative method to assess SSC competence of donor cell populations from larger animals is the use of xenogeneic transplantation of the donor cell population into the testis of an immunocompromised mouse recipient (Dobrynski et al., 1999; Dobrynski et al., 2000). This approach has been used for many large animal species and partially resolves the problems mentioned above. The first xenogeneic transplantation was demonstrated when rat SSCs were transplanted into immunocompromised mouse testes, and complete long-term rat spermatogenesis was reconstituted and generated functional spermatozoa (Clouthier et al., 1996). However, when germ cells from species more phylogenetically divergent from mouse, including rabbit, dog, cat, pig, cattle, horse, monkey, and human, were transplanted into infertile immunocompromised male mice, donor-derived spermatogenesis did not occur, but primitive spermatogonia from all the species examined colonized and proliferated for 1–12 months on the basement membrane of the recipient mouse seminiferous tubules. These cells are thought to be SSCs and undifferentiated spermatogonia. To reconstitute xenogeneic spermatogenesis in mice, species specific differentiation factors will be necessary, and transplantation of testicular somatic cell suspensions including Sertoli cells, in addition to SSCs from xenogeneic species, might reestablish the environment necessary for foreign species spermatogenesis in mice. However, xenogeneic transplantation is a valuable technique to assess the SSC colonizing and self-renewal ability of cell populations from non-rodent species and has been used to judge SSC competency of cell populations from those species.

Spermatogonial Transplantation as a Method to Determine SSC Competency of Cultured Cell Populations

Competency of Mouse SSCs in Culture

Development of culture systems to support self-renewal and expansion of SSCs is enormously valuable, and the spermatogonial transplantation assay has been indispensable to develop culture systems and to determine the SSC competency of any cell population. In 1998, long-term culture of murine SSCs was first demonstrated from an unfractionated population of testicular cells using STO (SIM mouse embryo-derived thioguanine and ouabain resistant) feeders in a serum-supplemented medium, and the SSCs were maintained for about 4 months (Nagano et al., 1998). Transplantation of the cultured cells resulted in donor cell-derived spermatogenesis in the recipient testes, indicating that SSCs existed in the long-term culture. The functional assay unambiguously demonstrated that SSCs could be maintained in culture for several months, although the culture condition was insufficient to support SSC maintenance in number. Subsequently, GDNF, which had been found to be a critical factor for spermatogonial proliferation in vivo (Meng et al., 2000), showed a beneficial effect on SSC maintenance in the culture condition; however, the SSC number rapidly decreased after 1-week in culture (Nagano et al., 2003). The first report of long-term ex vivo expansion of SSCs was from

mice with a DBA/2 genetic background cultured in a proprietary medium containing serum and several growth factors, including GDNF, FGF2, leukemia inhibitory factor (LIF), and epidermal growth factor (EGF) (Kanatsu-Shinohara et al., 2003). Using the enriched culture medium, gonocytes, precursors of SSCs in neonate testes, were cultured on mouse embryonic fibroblast feeder cells. Soon after the cultivation, DBA mouse gonocytes resumed proliferation and formed grape shape aggregates, which continuously proliferated. Because SSCs in adult testes are believed to behave as single cells, which are thought to be A_s spermatogonia, the aggregated cells did not look like typical spermatogonial cells. However, the transplantation assay unequivocally demonstrated that the aggregated cells possess SSC competency, because they generated donor-derived spermatogenic colonies following transplantation. Furthermore, progeny were produced by mating with female mice. The aggregating cells derived from DBA/2 mice were named germline-stem (GS) cells; however, GS cells were not established from other mouse strains such as C57BL/6 or 129/Sv.

Essential Factors for Rodent SSC Self-Renewal

Identification of essential mitogenic factors for self-renewing proliferation of SSCs is crucial to understanding SSC competence, and this can be accomplished by development of a defined SSC culture system and subsequent transplantation of the cultured cells (Kubota et al., 2004a, Kubota et al., 2004b). A system consisting of a serum-free defined medium containing minimum components and STO feeder cells demonstrated that GDNF is the essential growth factor for proliferation of SSCs. In the serum-free culture condition, undifferentiated spermatogonia from mouse testes formed morula-like, tightly packed cellular clumps, which continuously proliferate (Fig. 4A–D). Significant strain variation existed in development of long-term SSC cultures. While SSCs from DBA/2 mice require GDNF only for their continuous proliferation, SSCs from other mouse strains, such as C57BL/6 or 129/Sv require FGF2 and a soluble GDNF receptor GFRA1, which potentiates the GDNF stimulatory signal (Kubota et al., 2004b). The cell surface phenotype of proliferating clump cells was identical to undifferentiated spermatogonia in testes, and the functional assay demonstrated that their SSC competence is also equivalent to freshly isolated undifferentiated spermatogonia from testes (Kubota et al., 2004a), indicating that the clump-forming cells in the serum-free condition are functionally identical to SSC-enriched undifferentiated spermatogonia. Under the culture condition, the clump cells having SSC competence doubled every 5.6 days and continued to proliferate for more than 6 months (Kubota et al., 2004b). The recipient males transplanted with the cultured cells produced fertile progeny carrying the donor SSC haplotype (Fig. 5).

The culture system was improved further by reducing the oxygen concentration (Kubota et al., 2009). A low O₂ atmosphere (10% O₂) compared with an air atmosphere (21% O₂) enhanced self-renewal of SSCs in culture. In particular, SSCs from *W* mouse testes, which contain very few SSCs, could proliferate under the 10% O₂ condition, but not in an air atmosphere.

The simple serum-free culture system was applicable to cultivation of SSCs from rats, and the growth factor requirements for self-renewal of rat SSCs was also determined (Ryu et al., 2005). Like mouse SSCs, GDNF is the key growth factor for rat SSCs, and FGF2 enhanced their proliferation. Under culture condition containing GDNF, FGF2, and STO feeders, rat undifferentiated spermatogonia indefinitely proliferated as clumps (Fig. 4E), and cultured clump cells generated spermatogenic colonies in Busulfan-treated infertile recipients following transplantation. By mating with females, offspring with donor haplotype was successfully produced indicating that rat clump-forming germ cells possess the full competency of SSCs. An important finding arising from the rat experiments is that self-renewal of rat SSCs is dependent on GDNF, suggesting that this growth factor may be essential for SSC self-renewal in other species.

Characteristics and Competency of Rabbit SSCs in Culture

Although rodent SSCs have been investigated extensively using the culture and transplantation systems, knowledge about non-rodent SSCs is limited. The first long-term SSC culture of non-rodent mammals was from rabbit (Kubota et al., 2011). Mice and rats diverged phylogenetically about 11 million years ago, but rabbits diverged from rodents about 60 million year ago, similar to the divergence of large animals and primates from rodents. Thus, cultivation of rabbit germ cells could provide an excellent foundation for development of SSC cultures from other non-rodent species. While STO feeder cells used for rodent SSC cultures could not support clump formation and proliferation of rabbit spermatogonia, C166 feeder cells, a yolk-sac derived endothelial cell line, did support both when GDNF was present in the serum-free medium (Fig. 4F). When these clump-forming cells were transplanted into recipient immunocompromised mice, donor cells colonized and proliferated in the recipient testes for 6 months after transplantation (Kubota et al., 2011). Furthermore, the rabbit donor cells in recipient mouse testes retained their undifferentiated spermatogonial characteristics during this period. These results suggest that the clump-forming cells cultured on C166 feeders contained rabbit SSCs. To unequivocally demonstrate that they are rabbit SSCs, evaluation by transplantation into rabbit recipients is required.

Evaluation of SSC Competency of Domestic Animals and Primates in Culture

Continuous propagation of SSCs derived from large animals and primates, including human, is critical to develop new technologies of reproductive biology and therapeutic intervention for infertility (Kubota and Brinster, 2006). Reconstitution of donor-derived spermatogenesis by cultured SSCs of non-rodent animals followed by transplantation into the same species recipients has shown limited success. Currently, no long-term in vitro expansion of bona fide non-rodent SSCs has been reported. Therefore, the rabbit culture experiments serve as a model of initial assessment of the SSC competency of the cultured cells of non-rodent animals. There

Fig. 4 Long-term in vitro expansion of SSCs. (A–D) Initiation of clump-formation of undifferentiated spermatogonia and their continuous proliferation. Undifferentiated spermatogonia from 129/Sv mice were cultured on STO feeder cells. (A) 5 h, (B) 2 days, (C) 5 days, and (D) 5 months in cultures. The clump-forming germ cells retain SSC competency equivalent to undifferentiated spermatogonia from the testis. (E) Clump-forming germ cells developed from rat undifferentiated spermatogonia on STO feeders. (F) Clump-forming germ cells developed from rabbit undifferentiated spermatogonia on C166 feeder cells. Their SSC competency was confirmed by spermatogonial transplantation into rats (E) or immunocompromised mice (F). Scale bars: (A–D) 50 μ m, (E and F) 100 μ m. Modified from Kubota, H., Avarbock, M. R. and Brinster, R. L. (2004). are several studies of cultivation of putative SSCs from non-rodent species, which were evaluated by xenogeneic transplantation into immunocompromised mice (Kubota and Brinster, 2017). In most of the studies, donor cells in the recipient testes were characterized by immunohistochemistry or whole mount immuno-staining using SSC markers previously identified in rodents. Unfortunately, some of SSC markers of animals of interest were expressed in non-germ cells of primary and cultured testis cells; therefore, it was not clear that the colonized cells are indeed SSCs, which has resulted in controversy (Kubota and Brinster, 2017). Thus, for non-rodent SSCs the first step is identification of specific cellular or molecular markers of SSCs or undifferentiated spermatogonia in fresh testis samples, which can be used to identify colonized donor-cells in the recipient testes. Although the research on human SSCs is still in its infancy, phenotypic characterization of putative primate SSCs has been partially achieved (Her-mann et al., 2009). The identified molecular markers are valuable to characterize colonized putative primate donor-cells in recipients when potential SSCs in culture are transplanted. Short-term in vitro maintenance of clump cells of putative primate

Fig. 5 Schematic diagram of SSC culture and spermatogonial transplantation. A subpopulation enriched for SSCs from testes of transgenic mice expressing a fluorescent reporter gene (e.g. GFP) are cultured on STO feeders in a serum-free medium in the presence of GDNF. After expansion in culture, clump-forming germ cells are transplanted into infertile recipient males. Mating the recipient males to wild-type females results in production of progeny with the donor male haplotype. Genetic modification during cultivation can be employed. Modified from Kubota, H., Avarbock, M. R. and Brinster, R. L. (2004). Growth factors essential for self-renewal and expansion of mouse spermatogonial stem cells. *Proceedings of the National Academy of Sciences of the United States of America* **101**, 16489–16494.

spermatogonia has been achieved in preliminary results using the rabbit culture system (unpublished data). Xenogeneic transplantation of the clump cells into immunocompromised mice followed by characterization of colonized cells using molecular markers will provide reliable information for primate SSC characteristics. Nevertheless, evaluation of the SSC competency of the germ cell clumps is possible only by a functional transplantation assay; therefore, development of a functional assay to evaluate both the self-renewal and differentiation capacity using the same or phylogenetically-close species is essential for the future studies.

Concluding Remarks

Because stem cells are defined by their biological competence, development of a functional assay is crucial to explore their biology in depth. Since 1994, studies using spermatogonial transplantation have succeeded in clarify the identity of SSCs, function of the SSC niche, and factors influencing SSC competence, which was not possible without the approach. One of the most important achievements of the spermatogonial transplantation method is the development of culture systems that support ex vivo expansion of SSCs. The spermatogonial transplantation method in conjunction with in vitro culture systems maximizes the use of SSCs and allows development of new technology for male germline intervention and therapeutic treatments for male infertility in any mammalian species including humans.

Sex Chromosomes and Sex-Linked Genes in Spermatogenesis

Sex determination

A founding population of primordial germ cells are designated early in embryonic development. These cells migrate to the gonadal ridge, which are bipotential embryonic structures capable of developing into either male or female reproductive organs. Expression of the Y-linked sex determining gene *Sry* triggers differentiation of the embryonic gonads into testes (Berta et al., 1990). Individuals inheriting a Y chromosome lacking *Sry* are phenotypically female, and conversely those with an XX karyotype possessing a translocated *Sry* gene develop as males. As testes develop, secreted sex hormones—androgens—bind to the X-encoded *androgen receptor*, *Ar*, and drive the continued development of the male reproductive system. Another gene on the X chromosome, the nuclear receptor *Nr0b1* (previously known as *Dax1*), is also needed for development of testis cords and establishment of Sertoli and Leydig somatic cell.

Evolution of Sex Chromosomes

The mammalian X and Y are derived from an ancient pair of autosomes. Their role as sex chromosomes began 160–250 million years ago, following divergence of therians from monotremes, with the initial acquisition of *Sry* as a sex-determining gene. *Sry* is thought to have become a male determining factor resulting from a dominant mutation in the ancestral transcription factor *Sox3* (Graves, 2006). The acquisition of sex-specific genes created regions where the chromosomal pair could no longer recombine. Nonhomologous regions between X and Y impede meiotic pairing and the gene contents of nonrecombining regions decay rapidly over evolutionary time. The extant Y chromosome presents multiple “strata” resulting from consecutive rounds of rearrangement, loss of recombination, and degeneration (Lahn and Page, 1999).

The Y chromosome is much smaller than the X, and most of it composes a nonrecombining male-specific Y region (MSY) (Hughes and Page, 2015). A small stretch of X–Y homology, called the pseudoautosomal region (PAR), still exists. Synapsis and crossover formation at the PARs are critical for male meiosis. The human PARs represent about 5% of the genome yet contain about half the gene content of the Y chromosome. MSY is largely composed of segmental duplications creating palindromic regions, some of which are grouped and designated as azoospermia factor regions (AZF) due to their deletion being the frequent source of spermatogenic failure.

Dynamics of Gene Contents on the Sex Chromosomes

The gene content of the X chromosome is not constant. The X chromosome has an excess of genes expressed in testis, presumably because of its hemizygous status in males. The hemizygous status of X-linked genes in males provides rapid selection for X-linked recessive alleles that benefit males than heterozygous autosomal recessive alleles. Any new recessive allele is immediately selected for when located on the X in males. Even if the allele would be subject to purifying selection in females, sufficient rarity would make homozygosity unlikely, and thus male benefiting traits could become fixed regardless of their effect in females. As the frequency of this allele increases, any deleterious effect can be minimized by modulating the expression of the gene to be testis-specific. This sexual antagonism provides an explanation for spermatogenesis-related genes disproportionately populating the X chromosome (Wang et al., 2001).

Studies in marsupial mammals have provided examples for accumulation of testis genes on the X chromosome. *Nr0b1* encoding nuclear receptor DAX1 has a conserved function in gonadal development across all mammals (eutherians, metatherians, and prototherians), and as noted above is critical for the formation of the testis cord structure. The recruitment of *Nr0b1* to the X occurred only after divergence of placental mammals from marsupials, where it is expressed during gonadal development despite being autosomal (Stickels et al., 2015). This pattern of marsupial autosome to placental X chromosome recruitment for genes expressed in reproductive organs has been observed in several other genes. With recruitment of marsupial autosomal *TGIF* gene to the X chromosome in both human and mouse (*Tgiflx*), its expression also shifts from ubiquitous to an exclusively testis-specific pattern. As another example, *Arx* is autosomal in marsupials but X-linked in therian mammals. Although *Arx* is not testis-specific, it is expressed in germ cells in both marsupials and therians. Therefore, the role of *Nr0b1*, *Tgiflx*, and *Arx* in testis development was established prior to their translocation to the X.

Meiotic Sex Chromosome Inactivation (MSCI)

During the prophase of meiosis I, homologous chromosomes pair, synapse, and form crossovers. At the leptotene stage, homologous chromosomes pair and programmed DNA double strand breaks (DSBs) are generated to initiate meiotic recombination. At the

zygotene stage, homologous chromosomes begin to synapse through the synaptonemal complex. DNA damage response (DDR) proteins are recruited to DSBs and form discrete foci on meiotic chromosomes. DSBs are repaired and resolved at the pachytene stage, resulting in formation of crossovers. These crossovers yield the chiasmata evident in diplotene and diakinesis stages.

Meiosis occurs in both male and female germ cells but exhibits sexual dimorphism. In oocytes, the two X chromosomes pair without issue, as they are entirely homologous. In male meiotic germ cells, the X and Y chromosomes can only synapse at the pseudoautosomal regions, leaving the majority of sex chromosomes unsynapsed. At pachytene, unsynapsed chromatins are transcriptionally silenced. In the context of the X and Y chromosomes, this general surveillance process is referred to as meiotic sex chromatin inactivation (MSCI) (Turner et al., 2005).

MSCI is triggered by phosphorylation of the histone variant H2AX and the rapid recruitment of many DDR proteins. ATR catalyzes phosphorylation of H2AX (Royo et al., 2013). MSCI is marked with silencing histone modifications including H3K9me3 and is associated with incorporation of the histone variant H3.3. MDC1 and BRCA1 recruit BRCA2 and the ubiquitin ligase RNF8, and these in turn interact with a cascading network of DDR proteins (Alavattam et al., 2016). Through interactions with FANCD2, RNF8 links the BRCA and *Fanconi anemia* (FA) repair networks. As BRCA1 signal amplifies across the unsynapsed chromosomes, RNF8 recruits the FA proteins, changing the chromatin structure and initiating chromosome-wide gene silencing. The silencing of the sex chromosomes by MSCI is essential for progression through spermatogenesis. As discussed below, failure to initiate MSCI leads to meiotic failure.

Impact of MSCI on sex chromosome gene contents

As a direct consequence of MSCI, genes on sex chromosomes are enriched for those with expression in spermatogonia and early spermatocytes (Khil et al., 2004; Wang et al., 2001). Meiotic DNA double strand breaks are generated by the enzyme SPO11. In *Spo11* knockout testis, meiosis fails to progress to the pachytene stage of prophase I. Studies of *Spo11* knockout testes confirmed that premeiotically expressed genes are over-represented on the X chromosome.

Silencing of sex-linked genes during meiosis creates a need to compensate for critical X-linked genes. *Pgk1* is an X-linked gene encoding the phosphoglycerate kinase responsible for the conversion of glucose to pyruvate, a fundamental metabolic process. Coincident with *Pgk1* silencing during meiosis, an autosomal gene *Pgk2* is transcribed exclusively in the testis (McCarrey and Thomas, 1987). The *Pgk2* gene lacks introns and thus is a retrotransposed paralogue of *Pgk1*. Retrotransposition occurs when a processed mRNA is reverse-transcribed and reintegrated into the genome. The resulting copies are often nonexpressed pseudogenes, but some can become functional retrogenes. Genes on the X chromosome are parents to a disproportionately large number of retrogenes compared with autosomally derived copies (Emerson et al., 2004). X-derived retrogenes are more likely to be subject to positive selection than being autosomal, and this selection often favors male germline biased expression.

Many additional examples of X-to-autosome retrotransposition and subsequent testis specialization have been reported. TFIID is an essential component of the RNA polymerase holoenzyme. *TAF1* encoding a subunit of TFIID is X-linked. An autosomal retrogene paralogue *TAF1L* in humans is expressed specifically in the testis and is functionally equivalent to *TAF1* in a cell line (Wang and Page, 2002). A recessive mouse mutant called *juvenile spermatogonial depletion* (*jsd*) maps to an autosomal locus where a gene, *Utp14b*, contains a frameshift mutation (Bradley et al., 2004). The UTP14 protein functions in ribosome biogenesis. *Utp14b* is a testis-specific retrogene of the X-linked *Utp14a*. In humans, the X-to-autosome retrotransposition of *UTP14A* appears to have occurred independently. *Rpl10* is X-linked and encodes a ribosomal subunit (Jiang et al., 2017). *Rpl10* is expressed in early germ cells but not in spermatocytes at the pachytene stage and beyond. An autosomal retrogene copy, *Rpl10l*, is expressed specifically in the testis and in the same stage of germ cells where *Rpl10* is silenced. RPL10-deficient cells can be rescued by RPL10L. Further evidence for the functional substitution came from the generation of a mouse model expressing the X-linked *Rpl10* gene under control of the autosomal *Rpl10l* promoter. This transgene partially rescues spermatogenic defects in *Rpl10l*-deficient mice. These examples demonstrate that the X to autosome retrotransposition provides one important evolutionary mechanism to compensate for silencing of X-linked genes due to MSCI.

Multicopy Sex-Linked Genes and MSCI Escape

The gene content of the X chromosome across mammalian species is largely conserved. However, more than 300 genes differ between mouse and human X chromosomes (Mueller et al., 2013). Most of these genes were independently recruited to the X chromosome from autosomes. The majority of these genes are present as multicopy genes in ampliconic regions on the X chromosome. The mouse Y chromosome also acquired multicopy genes (Soh et al., 2014). While many sex-linked genes remain silenced postmeiotically, some sex-linked genes reestablish transcription in postmeiotic round spermatids (Namekawa et al., 2006). In particular, multicopy genes on the X and Y chromosomes escape postmeiotic silencing. These multicopy genes are preferentially expressed in postmeiotic germ cells. The absolute expression level per gene copy is low. Therefore, it has been hypothesized that the amplification of these sex-linked genes is to compensate for the continued silencing effect on sex chromosomes in postmeiotic germ cells (Mueller et al., 2013).

Hox genes are found in multigene clusters throughout the genome. They regulate developmental processes by functioning as *Homeobox* transcription factors. Following duplication, *Hox* genes are often found to acquire specialized expression profiles and

regulatory functions. A cluster of 12 *Hox*-related genes on the mouse X chromosome are referred to as *Rhox* genes owing to their expression in reproductive tissues (MacLean et al., 2005). Some of these *Rhox* genes have been individually inactivated in mouse. Inactivation of *Rhox5* leads to subfertility owing to defects in spermatozoa maturation (MacLean et al., 2005). *Rhox8* is exclusively expressed postnatally in Sertoli cells. Knockdown of *Rhox8* impairs male fertility. Disruption of *Rhox13* has no effect on fertility, although sperm count is reduced. The multicopy gene clusters on the sex chromosomes evolve rapidly and are often divergent between species. In comparison with the mouse *Rhox* cluster, the human *RHOX* locus contains only three gene copies.

Multicopy gene families present a challenge to characterizing both the structure of the genome and determining its physiological functions. The repetitive nature of regions produced by segmental duplication confounds genome assembly, although strategies have been developed to enable sequencing of complex regions on the sex chromosomes (Mueller et al., 2013; Soh et al., 2014). A genetic approach of knocking out individual genes is ineffective for assessing the function of some multicopy gene clusters, because of functional redundancy. One successful method adapts Cre/loxP-mediated genome editing to deleting large regions containing multicopy genes. Humans with a 1.1 Mb deletion on the X chromosome (Xq22.1 deletion syndrome) develop a range of symptoms including epilepsy, mental retardation, and cleft palate. Mice lacking the syntenic region of the X chromosome phenocopied the human deletion syndrome (Zhou et al., 2014). Among the 20 genes deleted between *Nxf2* and *Nxf3* are five near identical genes in the *preferentially expressed antigen in melanoma* (*Pram*) family and several closely related copies of *Gm6215* along with multiple pseudogene copies. Many genes in this region are specifically expressed in testis. Germline-specific deletion of this region results in meiotic defects and male sterility. While a defect in chromosomal synapsis was characterized, a specific gene or gene family within the deleted region is yet to be identified. This study demonstrates that large scale deletions and subdeletions present one method for genetically characterizing the roles of multicopy gene families.

The *Sly* (Sycp3-like Y-linked) gene is present in multicopies in the MSY region of the mouse Y chromosome. As many as 70 of the ~100 copies contain open reading frames, suggesting that they may encode functional proteins. Knocking down *Sly* transcripts with silencing RNAs (siRNA) shows that SLY plays a role in maintaining postmeiotic silencing of the sex chromosomes. By directing heterochromatin formation, SLY helps repress sex-linked spermatid genes, including itself. Therefore, amplification of this gene on the Y may be, in part, a response to its self-silencing effect.

Knocking down *Sly* upregulated, among other genes, the multigene X-linked *Slx* (homologous to *Sly*) family of genes (Cocquet et al., 2012). Where SLY proteins localize to the nucleus and specifically to the sex chromosomes, SLX protein products are cytoplasmic. *Slx* transcripts were knocked down with a similar shRNA-mediated approach as developed for *Sly*. Knockdown of this gene family does not alter sex chromosome silencing, but affects sperm maturation and release into the seminiferous lumen. These X and Y chromosome multigene families are closely related. When SLY proteins are reduced, SLX proteins localize to the nucleus and appear to fill the vacated role of chromatin remodeling (Cocquet et al., 2012). Knocking down *Sly* corrects the gene regulation defects caused by knocking down *Slx*. Mice lacking both *Slx* and *Sly* gene products have better sperm maturation and fertility than knockdown of either *Slx* or *Sly* gene family alone. These studies reveal an intragenomic conflict between the X and Y chromosomes in postmeiotic germ cells.

X-Linked MicroRNA Gene Families

MicroRNAs are 22-nucleotide RNAs processed from longer primary transcripts, and are involved in translation repression and gene silencing. The density of miRNA clusters is significantly higher on the X chromosome than the autosomes. The evolution and expression of miRNAs on the X chromosome share common features with protein-coding genes discussed above. Clusters of many paralogous miRNA copies are found on the X chromosome because of recent rapid divergence. The testis expresses miRNAs from across the genome, however X-linked multimember miRNA families are more highly expressed in spermatocytes and spermatids than autosomal ones. The X-linked testis-expressed microRNA clusters are rapidly evolving, showing a substitution rate 25 times greater than autosomal clusters.

Transcription of X-linked microRNA genes is subject to MSCI (Royo et al., 2015; Song et al., 2009). Some miRNA genes on the X chromosome that have expanded by gene duplication are able to escape transcriptional silencing. Similar to MSCI-escaping protein coding genes, these microRNA genes transcribe primary transcripts through the pachytene stage. However, RNA FISH has shown that X-linked microRNA genes are silenced by MSCI and that the misexpression of these miRNAs in pachytene spermatocytes causes spermatogenic defects (Royo et al., 2015). As observed for protein coding genes, some X-linked miRNA genes have nearly identical copies on autosomes, which may substitute for their loss during MSCI.

Role of Y-Linked Genes in Spermatogenesis

The Y chromosome is dispensable for survival, but is crucial for male sex differentiation and spermatogenesis. *Sry* drives testis development and thus determines the male sex. Other Y-linked genes are not involved in sex determination but are important for spermatogenesis. The identification of Y-linked genes involved in spermatogenesis relied on mutants with naturally occurring segmental deletions of the Y chromosome. Functional requirements of candidate genes identified in the Y chromosome deletion region were tested by transgenic expression in mice with the Y chr deletion. One such study systematically examined genes lost in a sterile mouse model with a deletion on the Y chromosome. One Y-linked gene, *Eif2s3y*, was found to be essential for spermatogenesis (Mazeyrat

Table 1 Mouse sex-linked genes involved in spermatogenesis.

Gene symbol	Knockout phenotype	Chr
<i>Akap4</i>	Shortened sperm flagellum and impaired motility	X
<i>Ar</i>	Meiotic arrest at the pachytene stage	X
<i>Cdk16</i>	Defective sperm morphology and impaired motility	X
<i>Fmr1</i>	Chromosome asynapsis and impaired crossover formation	X
<i>Gcna</i>	Male sterility	X
<i>Nr0b1</i>	Testis cord formation defect; rete testis blockage	X
<i>Nxf2</i>	Reduced spermatogonial proliferation; meiotic arrest	X
<i>Prdx4</i>	Increased spermatogenic cell death due to oxidative stress	X
<i>Rhox5</i>	Increased male germ cell apoptosis; reduced fertility	X
<i>Scml2</i>	Defective spermatogenesis; reduced fertility	X
<i>Slx/Slx1-1</i>	Delayed sperm release; increased spermatid apoptosis	X
<i>Sox3</i>	Impaired differentiation of spermatogonia	X
<i>Taf7l</i>	Reduced male fertility; defects in sperm morphology	X
<i>Tex11</i>	Meiotic failure	X
<i>Tsc22d3</i>	Loss of male germ cells	X
<i>Tsx</i>	Increased apoptosis in spermatocytes	X
<i>Eif2s3y</i>	Defect in spermatogonial proliferation	Y
<i>Sry</i>	Male to female sex reversal	Y
<i>Zfy1/Zfy2</i>	Defects in sperm morphology	Y

et al., 2001). Through in vitro fertilization, only two Y-linked genes, *Sry* and *Eif2s3y*, are found to be required for development of the testis and normal spermatogenesis through the end of meiosis (Yamauchi et al., 2014). However, the mice with only two Y-linked genes (*Sry* and *Eif2s3y*) can produce some round spermatids but do not complete spermiogenesis.

Two Y-linked genes, *Zfy1* and *Zfy2*, are important for efficient MSCI and also function as a checkpoint for sex chromosome silencing during meiosis. Genes on the X and Y chromosomes escape MSCI in mice lacking *Zfy1/Zfy2*. Targeted deletion of Y-linked genes in embryonic stem (ES) cells through homologous recombination was not successful for unknown reasons. Recently, the CRISPR/Cas9 genome-editing approach has been successfully used to delete *Zfy1* and *Zfy2* in mouse (Nakasuji et al., 2017). Disruption of either gene alone has no effect on fertility. However, *Zfy1/2* double knockout mice are male sterile and show defects in sperm morphology, suggesting that these two Y-linked genes function complementarily in spermiogenesis (Table 1).

Role of X-Linked Genes in Spermatogenesis

The X chromosome contains a large number of testis-specific genes. Gene knockout approach has been informative in elucidating their functions (Table 1). Males produce sperm throughout life, because of the presence of spermatogonial stem cells. Spermatogonial stem cells proliferate, self-renew, and sustain continuous spermatogenesis. X-linked genes have been identified with critical roles at each stage of spermatogenesis. The nuclear mRNA export factor *Nxf2* and phosphatidylcholine biosynthesis protein *Pcyt1b* are both X-linked genes affecting spermatogonial proliferation. Defects in proliferation often do not impact the first wave of spermatogenesis in juveniles. Instead germ cells are depleted as spermatogonia enter meiosis without replacing themselves. Therefore, mice lacking either *Pcyt1b* or *Nxf2* progressively lose germ cells with age. In addition, *Nxf2* also regulates meiosis in spermatocytes, depending on the genetic backgrounds.

A number of X-linked genes regulate meiosis including *Fmr1*, *Tex11*, and *Scml2* (Table 1). Meiotic recombination involves formation of programmed DNA double strand breaks and subsequent repair of these breaks. The *Fragile X mental retardation protein* gene, *Fmr1*, regulates protein translation in the cytoplasm of neurons, and is also involved in the DNA damage response to meiotic double strand breaks in gametogenesis (Alpatov et al., 2014). Disruption of *Fmr1* impairs chromosome synapsis and crossover formation. TEX11 interacts with SYCP2, a component of the synaptonemal complex. TEX11 localizes as foci along the synaptonemal complex on meiotic chromosomes. TEX11 promotes chromosomal synapsis and meiotic recombination. *Tex11* knockout male mice are sterile. Some chromosomes in *Tex11*-deficient spermatocytes fail to synapse, leading to meiotic arrest and apoptosis. Additionally, *Tex11*-deficient spermatocytes form fewer crossovers, which leads to the formation of univalent chromosomes and chromosome missegregation. Testes from humans with mutations in the *TEX11* gene also display meiotic arrest (Yang et al., 2015). Germ cell specific polycomb protein, SCML2, is a critical chromatin remodeling factor during spermatogenesis (Hasegawa et al., 2015; Luo et al., 2015). SCML2 is expressed in spermatogonia and spermatocytes. In pachytene spermatocytes, SCML2 localizes to the sex body and recruits a deubiquitinating protein, USP7 to modulate histone ubiquitination in the XY chromatin. It is intriguing that these X-linked genes (*Fmr1*, *Tex11*, and *Scml2*) are presumably subject to MSCI but function in meiosis, suggesting the existence of additional developmental and posttranscriptional mechanisms in coping with MSCI.

Following meiosis, spermiogenesis proceeds with extensive chromatin remodeling, formation of an acrosome, and development of the sperm tail. Targeted deletion of *Akap4*, an X-linked gene expressed in spermatids, does not affect the number of sperm produced (Miki et al., 2002). However, maturation of sperm lacking this structural protein was severely impacted. AKAP4-deficient sperm display short abnormal tails and lack motility. Sperm from mice lacking the X-encoded protein kinase gene, *Cdk16*, also display a range of morphological abnormalities and impaired motility. Both of these X-linked knockout males are infertile. In sum, genetic studies have shown that X-linked genes, particularly testis-specific genes, function throughout spermatogenesis: mitotic proliferation, meiosis, and postmeiotic differentiation.

Sex-Linked Genes and Spermatogenic Failure in Humans

Some sex-linked genes discussed here are implicated in spermatogenic failure in humans. Mutations in *SRY* or the X-linked androgen receptor gene, *AR*, are responsible for cases of sex reversal (Jager et al., 1990; Lubahn et al., 1989). As mentioned in the previous section, mutations in the X-linked meiosis gene *TEX11* leads to meiotic arrest and nonobstructive azoospermia (Yang et al., 2015). Clinical analysis of infertile men presenting sperm with fibrous sheath dysplasia identified mutations in *AKAP4*.

The Y chromosome has multiple azoospermia factor regions (AZF) associated with male infertility: AZFa, AZFb, and AZFc. In the AZFa region, deletions lead to a Sertoli cell only phenotype, due to a complete loss of germ cells. Work in induced pluripotent stem cells (iPSC) suggests this phenotype is due to loss of *DDX3Y*, which is primarily expressed in spermatogonia. Deletion of the AZFb region causes infertility due to spermatocyte arrest. Deletion of the AZFc region, containing the *DAZ* genes, is associated with highly variable testicular defects (Reijo et al., 1995). These human studies demonstrate the important role of sex-linked genes in human sex differentiation and reproductive fecundity.

The Cycle of the Seminiferous Epithelium

Michael D Griswold, Washington State University, Pullman, WA, United States

The formation of spermatozoa via spermatogenesis is a continuous process throughout the reproductive lifetime of most mammals. The end products (sperm) are expelled (spermiation) from the testis and the next generation of sperm begin to develop from spermatogenic stem cells. In order to maintain the continuum of sperm production, the initiation of spermatogenesis and spermiation are coordinated. In most mammals the time required to generate spermatozoa from spermatogenic stem cells is about 30–40 days. The complexities of spermatogenesis are best known in the mouse but appear to be similar in most mammalian species. The testicular germ cells all arise from a population of spermatogenic stem cells that proceed through a well-defined differentiation process. In the mouse, the first pool of cells formed from the spermatogenic stem cells are termed the “progenitor spermatogonia” or “undifferentiated spermatogonia” (Oatley and Brinster, 2006, 2008). The term “undifferentiated spermatogonia” is a misnomer in that these cells are committed to the spermatogenic lineage. This pool acts as a reservoir of undifferentiated spermatogonia (progenitor cells) that replicate and undergo incomplete cytokinesis to form clonal chains of 2, 4, 8, or 16 cells connected by intracellular bridges. The pool of progenitor cells can be maintained for a period of time without undergoing differentiation but when acted on by retinoic acid (RA) the chains of progenitor cells immediately enter an irreversible differentiation pathway (Griswold, 2016). Once acted on by retinoic acid the clonal progenitor cells form differentiating spermatogonia that undergo a series of highly synchronized, controlled and irreversible cell divisions and differentiation steps that result in the formation of preleptotene spermatocytes. The preleptotene cells while maintaining the clonal structure undergo meiosis and spermiogenesis in additional tightly controlled events. The transition of differentiating spermatogonia also termed “A₁ spermatogonia” from progenitor cells as a result of the action of RA can be considered the initial committed step in spermatogenesis that will lead 35 days later to the release of spermatozoa in the mouse.

The key to murine reproduction is the rapid and efficient production of gametes so while the development of A₁ spermatogonia to the point of spermiation takes 35 days, the initiation of the process occurs four times more frequently (every 8.6 days in the mouse). The net result is that at any point along the seminiferous tubule there are multiple developing cell types present. The periodic and frequent initiation of the A₁ transition of spermatogonia results in a buildup of the germ cell component with the more advanced cells being moved towards the tubule lumen. The end result after 35 days are multiple germ cell layers consisting of four distinct differentiating germ cell types with spermiation occurring into the lumen of the tubule and initiation of the next round of spermatogenesis at the basal aspect of the tubule.

The linear development of germ cells over 35 days with the initiation of the A₁ transition occurring every 8.6 days results in the same grouping of germ cells being continuously repeated over time. There are 8.6 days between spermiation/initiation events and in this time each layer of cells undergoes a series of developmental steps that result in recurring groups of morphologically distinct cells found interrelated with each other (cell associations). In Fig. 1 the murine linear germ cell development is shown in more detail with each 8.6 day window shown as a blue rectangle. It is apparent from Fig. 1 that each 8.6 day period results in a series of repeating cellular associations. It is these repeating cellular associations that give rise to the 12 stages of the cycle of the seminiferous epithelium of the mouse shown in the expanded view of an 8.6 day period (Clermont, 1972; Leblond and Clermont, 1952). The number of identifiable stages in the cycle for any given species is determined solely by the morphology of the developing germ cell types. The length of one cycle is determined by the time between the transitions of undifferentiated spermatogonia to differentiating spermatogonia. If the cycle of the seminiferous epithelium from many different species is examined several commonalities can be seen. First, the A₁ transition, the onset of spermatid development and spermiation are linked to the same or closely aligned stages and four rounds of the cycle are required for the development of sperm from the onset of spermatogonial differentiation. This relationship suggests a possible common signaling mechanism for these events.

The description of the cycle thus far has focused on a single point along the seminiferous tubule and how the cell population changes with time. If the transition of undifferentiated to differentiating spermatogonia occurred at the same time in all tubules, spermatozoa would be released only every 8.6 days. This type of spermatogenesis is termed synchronous as opposed to the normal asynchronous timing. The initiation of the cycle as a result of the A₁ transition of spermatogonia is staggered along the tubule in a continuous and progressive manner. The net result is the continuum of stages of the cycle in space and the distance from one stage to a repeat of that stage constitutes the spermatogenic wave (Fig. 2). The spermatogenic cycle (repeating cellular associations with time) and the wave (repeating cellular associations along the tubule) are similar in most mammals but differ somewhat in humans and great apes. When it was shown that a cross section of a seminiferous tubule contained more than one stage of the cycle in great apes and humans, it was proposed that this was the result of a helical orientation of several spirals of spermatogenic waves (Luetjens et al., 2005; Wistuba et al., 2003). The concept of a spiral or helical arrangement of the stages to form a wave has also been challenged (Johnson, 1994).

The key factor in the formation of differentiating spermatogonia or the A₁ transition is retinoic acid. In the absence of retinoic acid the undifferentiated spermatogonia are the most advanced cell type in the testis. The presence of retinoic acid stimulates a rapid and defined progression of undifferentiated to A₁ spermatogonia that move through spermatogenesis to ultimately form

Fig. 1 (Top) Generating the recurring cellular associations that define the cycle of the seminiferous epithelium. The cycle is generated by the precisely timed transition of A spermatogonia into A₁ spermatogonia (red circle). In the mouse this transition occurs every 8.6 days. In addition it takes 8.6 days for the A₁ spermatogonia to become preleptotene spermatocytes and enter meiosis and an additional 8.6 days $\times$ 3 to form elongated spermatids ready for spermiogenesis. The net result is that once fully established the same cell associations or the same group of cell types appears every 8.6 days (designated by blue rectangles). In the 8.6 day period between the transition of A spermatogonia to A₁ spermatogonia there is a continuum of development of each cell type. Red (differentiating A₁ spermatogonia), green (preleptotene spermatocytes), yellow (pachytene spermatocytes), orange (round or elongating spermatids), magenta (elongated spermatids). The red arrows designate the timing of the pulses of retinoic acid that initiate the differentiation. In the bottom of the figure one blue rectangle is expanded to illustrate the cycle as it is normally pictured.

spermatozoa. In the normal murine testis there are pulses of retinoic acid that move progressively along the tubule to both stimulate the initiation of the cycle of the seminiferous epithelium and the release of spermatozoa (spermiogenesis).

The timing of the cycle is dependent on the time required to form spermatozoa and the frequency of retinoic acid pulses and therefore is species specific. However, the function of the cycle is to assure nonsynchronous and continuous spermatogenesis as opposed to synchronous and pulsatile release of sperm.

Fig. 2 Depiction of a spermatogenic wave. A section of a seminiferous tubule is shown with the distribution of stages of the cycle shown to be progressively aligned along the tubule. The wave is created by the movement of pulses of retinoic acid (*red arrow*) moving along the tubule.

Introduction

The functions of the sperm are to transport and contribute a haploid copy of the paternal genome to the egg and initiate development of the embryo. To achieve this goal efficiently, the structure of the sperm cell has evolved to be compact and compartmentalized. The spermatozoon can be divided into two major, morphologically distinct compartments, the head and the tail (flagellum) (Fig. 1). The head can be further subdivided into the acrosomal region and the nucleus. The acrosomal region includes the secretory acrosomal vesicle and the plasma membrane overlying the acrosome. This structure is involved in acrosomal exocytosis, zona pellucida binding, and sperm binding/fusion to the plasma membrane of the oocyte. The nucleus contains a copy of the paternal genetic material to be transported to the oocyte. The flagellum is often termed the “powerhouse” or “motor” of the sperm cell. This structure produces energy by glycolysis and oxidative phosphorylation which is used by the motile machinery in the tail to propel the sperm through the female reproductive tract and oocyte investments. The flagellum can be structurally segmented into four distinct, concatenated regions that are termed the connecting piece, the midpiece, the principal piece, and the end piece. The entire sperm cell is encased by the plasma membrane.

Sperm from diverse species may be structured differently and vary considerably in length. For example, in rodent sperm, the centrosomes and the centrioles are missing (Goto et al., 2010). In most other species, a reduced form of the centrosome with a single proximal centriole is present. In rodent sperm, the head is falciform or “hook-shaped.” In many other mammalian species, including ungulates, carnivores, and primates, the heads are spatulate or “oval-shaped.” The human sperm cell is about 60 μm long, and the flagellum is greater than 1 μm in diameter, 55 μm in length, and tapers toward the end piece. Among rodents, the sperm length varies. In the mouse, the sperm is about 120 μm in length, and rat sperm is about 190 μm long. The Chinese hamster has one of the longest mammalian sperm cells at 250 μm . The rabbit and sea urchin produce some of the shortest sperm that are 46 and 50 μm long, respectively (Eddy, 2006). On the other hand, the longest spermatozoon described to date is from the fruit fly, *Drosophila hydei*, at about 23 mm in length (Pitnick and Markow, 1994)! It should also be noted that some sperm, such as the

Fig. 1 Generalized picture of a mammalian sperm based on the guinea pig. The head and flagellum are indicated as are the major subdivisions of these organelles. CP: connecting piece. Green structures in the midpiece represent the mitochondria. Blue line running through the tail represents the axoneme and the red and reddish-orange structure in principal piece represent the longitudinal columns and circumferential ribs of the fibrous sheath, respectively. Orange represents the nucleus. Light gray and dark gray represent the apical and principal-equatorial segments of the acrosome, respectively.

amoeboid sperm from the round worm *Caenorhabditis elegans*, lack a flagellum (Nelson et al., 1982). Although sperm cells are generally uniform in size and shape within most species, abnormalities of morphology can exist within individuals, which may lead to subfertility or infertility.

Sperm Head

The mammalian sperm head contains the nucleus, which is capped at its anterior end by a single secretory vesicle called the acrosome (Fig. 2). During the course of spermatogenesis, the nucleus becomes extensively condensed and residual cytoplasm is removed from the cell body, resulting in a tightly compact, mature spermatozoon. In the head, the nucleus is surrounded by moderate amounts of cytoskeletal components and a very small volume of cytoplasm. Cytoskeletal components lie in the narrow space between the acrosome and the nucleus as well as between the acrosome and the plasma membrane.

Nucleus

During spermatogenesis, the chromatin is extensively remodeled. The histones associated with the deoxyribonucleic acid (DNA) are largely replaced by protamines in the sperm nucleus. Protamines are positively-charged, DNA-binding proteins that facilitate the packaging of the sperm chromatin into a compact hydrodynamic nucleus enabling the transport of a haploid copy of the male's genome to the oocyte (Brewer et al., 2002; Dadoune, 2003). The nuclear volume is less than 5% of that of a somatic cell, and the chromatin is extensively condensed to 1/13th that of the oocyte nucleus (Martins and Krawetz, 2007). The nucleus is covered by a nuclear envelope. Except for some species with redundant nuclear envelope material containing nuclear pore complexes at the base of the sperm nucleus, the nuclear pore complexes are removed during spermatogenesis (Ho and Suarez, 2003). The nuclear lamina is a protein meshwork lining the inner surface of the nuclear envelope (Elkhatib et al., 2015). It forms part of the nuclear skeletal network anchoring the chromatin and is made up of lamins, which are members of the intermediate filament family of proteins. The perinuclear theca forms a rigid shell composed of disulfide bond-stabilized structural proteins incorporated with numerous other protein molecules (Korley et al., 1997).

Acrosome

The acrosome is a Golgi-derived, membrane-enclosed vesicle that forms a cap in the proximal segment of the sperm head (Figs. 1 and 2). Morphologically, the acrosome consists of three segments: *apical*, which extends beyond the anterior aspect of the nucleus; *principal*, which overlies the anterior aspect of the nucleus; and *equatorial*, which forms a thinner posterior band around the nucleus.

Fig. 2 Diagram of the nucleus and acrosomal regions of the guinea pig sperm. On the *left*, a longitudinal section through the head shows that the acrosome can be delineated into three major zones: apical, principal, and equatorial segments. The central diagram shows the various membrane domains: PM, plasma membrane; OAM, outer acrosomal membrane; IAM inner acrosomal membrane; and NM, nuclear membrane. Also shown is the perinuclear theca (PT) that lies between the inner acrosomal membrane and the nuclear membrane. The nucleus is colored *orange*. The figure on the right shows a dorsal view of the sperm head.

Biochemically, the contents of the acrosome can be considered to be of two general states: freely soluble or insoluble (matrix or membrane-associated). Some of the proteins found in the acrosome are thought to be necessary for sperm binding to or penetration of the oocyte zona pellucida or to be required for the dissolution of the insoluble acrosomal matrix (Gerton, 2002; Yoshinaga and Toshimori, 2003). The membrane enclosing the acrosome can be demarcated into the inner acrosomal membrane, which is laminated to the nuclear envelope, and the outer acrosomal membrane, which is apposed to the inner face of the plasma membrane overlying the acrosome. The distinctions of these two zones are set up during early spermiogenesis when the membrane of the pro-acrosomal vesicle contacts and then flattens against the nuclear envelope, forming the inner acrosomal membrane. As spermiogenesis proceeds, the expanding acrosomal vesicle continues to spread over the apical end of the nucleus as spermatid elongation occurs (Hermo et al., 1980). Some proteins of the acrosomal matrix associate with the inner and/or outer acrosomal membranes; in addition, they may partition within specific zones of the matrix. Like other Golgi-derived vesicular elements, the acrosomal membranes contain glycoproteins like IZUMO1 (the inner acrosomal membrane, oolemma-binding protein (Inoue et al., 2005)) which have specific functions in gamete fusion. During acrosomal exocytosis, the outer acrosomal membrane fuses with the overlying plasma membrane and the newly created hybrid vesicles are shed from the sperm while the inner acrosomal membrane remains intact and becomes a new part of the plasma membrane in that region of the sperm head.

Acrosomal shape and size vary widely between species (Fawcett, 1970). In animals with a spatulate, oval-shaped, sperm head, the acrosome is flattened in the plane of the lateral (x) and anterior-posterior (z) axes of the sperm cell. In contrast, mureoid rodent sperm cells, such as those from mouse, rat, and hamster, have a falciform or hooked-shaped head containing an acrosome that overlies the convex and, to a lesser extent, concave margins of the nucleus; the nuclei of these cells are flattened in the y-axis. Conversely, sperm from caviid rodents such as guinea pigs start out with a spatulate morphology that morphs during epididymal maturation into a cupped shape that resembles the jai alai basket known as a *cesta*; in longitudinal section (yz plane), these sperm appear to have falciform-shaped heads. The acrosomes of guinea pig sperm are quite large and the apical segments can be readily isolated, making these sperm an excellent model for studying the biochemistry of acrosomal dynamics.

Cytoskeletal, Cytoplasmic, and Membrane Distinctions

Various terms have been utilized to describe extra-nuclear and extra-acrosomal regions of the sperm head and the reader is warned that the use of these terms may vary slightly among different investigators. The plasma membrane region that is in close association with the outer acrosomal membrane may be described by the term *periacrosomal* (from the Greek *peri* meaning “about, around”) (Flaherty and Olson, 1988). Cytoskeletal and cytoplasmic regions can be considered as three specific compartments: *subacrosomal* (between the inner acrosomal membrane and the nuclear envelope), *postacrosomal* (between the plasma membrane and posterior nucleus), and *para-acrosomal* (the cytoplasmic/cytoskeletal region adjacent to the outer acrosomal membrane) (Eddy, 2006). The *perinuclear theca* is a sheath that encases the full extent of the sperm nucleus; it can be further subdivided into the postacrosomal perinuclear theca and the subacrosomal perinuclear theca. The *perforatorium* is a specialized structure found in the apical region of the subacrosomal perinuclear theca. Each segment serves a distinct function. For example, the subacrosomal layer of the perinuclear theca functions to anchor the acrosome to the anterior region of the nucleus.

Sperm Flagellum

The biogenesis of the mammalian sperm flagellum is an orderly process that occurs during spermiogenesis, the last phase of spermatogenesis when the haploid spermatids differentiate into spermatozoa. Immediately following the completion of meiosis, each round spermatid elaborates a primitive flagellum, which initially consists of the *axoneme* surrounded by the plasma membrane. Subsequently, the remaining three major flagellar accessory structures, *outer dense fibers*, *mitochondrial sheath*, and *fibrous sheath*, are produced in a temporally-regulated manner. Since the axoneme is the key for flagellar structure, it will be addressed first.

The Axoneme: The Foundation for Flagellar Structure and Function

The axoneme extends from the connecting piece along the full length of the flagellum and generates the propulsive force for sperm cell movement (Figs. 1 and 3). In addition to numerous other proteins, the major components of the axoneme are cytoskeletal tubulins and dynein motor proteins. The axonemal structure is composed of nine circumferentially arranged outer microtubular doublets and two central microtubular singlets (canonical “9 + 2” arrangement of microtubules), composed of dimers of α -tubulin and β -tubulin. Each doublet consists of an “A microtubule” and a “B microtubule.” The B microtubule is configured in a C-shaped and attaches onto the side of the A microtubule. On cross section, two dynein arms extend from the A microtubule toward the B microtubule of the next microtubular doublet. In most mammals, the central pair of microtubules extends longitudinally from the implantation fossa through the connecting piece to the end piece, whereas the other microtubules travel from the remnants of the base of the distal centriole to the end piece. Radial spokes are structures that extend from the base of the A microtubules to the central pair (Fig. 3D) (Inaba, 2011).

Fig. 3 Diagram of the four major regions of the mammalian sperm flagellum in cross section. (A) Connecting piece (based on the study of Ounjai et al. (2012)). (B) Midpiece. (C) Principal piece. (D) End piece. The numerals in D represent the numbers assigned to the outer doublets of microtubules.

Flagellar Segments and Their Accessory Structures

Connecting piece

The flagellum fastens to the base of the sperm head by the *connecting piece* (Fig. 3A). The *implantation fossa* is a specialized domain of the posterior nucleus that adheres to the proximal face of an electron dense structure of the connecting piece, known as the *basal plate*. Additionally, the *capitulum* initiates at the distal face of the basal plate, conforming to the shape of the implantation fossa. The connecting piece retains some centriolar proteins, which act to stabilize the proximal part of the flagellum (Ounjai et al., 2012; Woolley et al., 2008). In most mammals, except rodents, the capitulum contains the proximal centriole, which is a remnant of the bi-centriolar centrosome found in early haploid spermatogenic cells. The complete degradation of both centrioles during spermiogenesis distinguishes rodents from other species. The centrosome is an amorphous cytoplasmic region approximately 0.5 μm in length and 0.2 μm in diameter that functions as the primary microtubule organizing center and regulates the nucleation and spatial organization of microtubules.

The capitulum is contiguous with the *segmented or striated columns*. At the zone where the connecting piece transitions into the midpiece, there are nine striated or segmented columns, held together by filamentous linkages. The segmented columns extend 1–2 μm posteriorly from the capitulum and connect at their distal ends to the outer dense fibers, cytoskeletal structures that continue into the midpiece and principal piece segments. At the proximal end, the segmented columns fuse with each other to form the centriolar vault, created by the disintegration of the proximal centriole. At the distal end, the segmented columns meld with the outer dense fibers to form the distal centriolar vault, organized by outer dense fibers 3 and 8 that associate with a bar-like structure.

Midpiece

The *midpiece* of the sperm flagellum is distinguished by its relatively greater thickness compared to the more distal principal piece (Fig. 3B). The midpiece is bordered at its anterior aspect by the connecting piece and at its posterior limit by the annulus, a transverse ring of dense material. Mitochondria and the outer dense fibers are key accessory structures of the midpiece.

There are nine outer dense fibers and these are located between the mitochondrial sheath and the axoneme (Fawcett, 1975). They are numbered corresponding to the adjacent outer microtubule axonemal doublets from which they emanate. The outer dense fibers adhere to the connecting piece at the proximal end of the flagellum and, generally, run longitudinally the full length of the midpiece and most of the principal piece. The exceptions to this rule are outer dense fibers 3 and 8, which are replaced by the longitudinal columns of the fibrous sheath in the principal piece. Outer dense fibers 1, 5, 6, and 9 are larger in cross section than fibers 2, 3, 4, 7, and 8. In the proximal region of the midpiece, the outer dense fibers start out thick and then gradually taper in size as they progress toward the flagellar end piece. They terminate in the proximal half of the principal piece in primate sperm but extend to near the end of the principal piece in rodent sperm (Fawcett, 1975). The last to be curtailed are the large outer dense fibers 1, 5, and 6. Electron microscopy has determined that each outer dense fiber is composed of a cortex and medulla. The cortex is a thin layer and seems to be composed of a single lamina of globular particles 6–7 nm in diameter; whereas, the medulla appears electron dense with no obvious substructure (Olson and Sammons, 1980). The cortex appears to be continuous with the satellite fibers that are present in the flagellar matrix at the surface of the outer dense fibers facing the axoneme (Irons and Clermont, 1982).

The predominant characteristic of the midpiece is the sheath of mitochondria wrapped in a spiral pattern around the nine outer dense fibers that form intimate associations with the outer microtubular doublets of the axoneme. In most species, the structure of the mitochondrial sheath is highly uniform. The midpiece length is related to the length of the sperm cell. In most mammals it is between 5 and 12 μm , but in rats and Chinese hamsters, the midpiece is 64 and 100 μm long, respectively (Baccetti, 1982, 1986). Sperm mitochondria are elongated and flattened compared to those found in somatic cells. The number of helices made by the mitochondria and the lengths of the midpieces vary among species (Eddy, 2006). Each sheath consists of approximately 75–100 mitochondria that are degraded by targeted proteolysis once the sperm flagellum has been drawn inside the fertilized ovum; as a consequence, the mitochondrial genome is inherited maternally (Sutovsky et al., 2004). In the midpiece, the mitochondrial sheath adheres to an underlying complex of filaments named the sub-mitochondrial reticulum (Olson and Winfrey, 1990). This complex is a network of ribbons of filamentous material that are laterally interconnected. The sub-mitochondrial reticulum terminates and fuses with the *annulus* at the junction between the midpiece and the principal piece.

Principal piece

Just posterior of the annulus, the principal piece begins and continues for most of the remainder of the flagellar length (Fig. 3C). Mitochondria are not found beyond the annulus although the axoneme and seven of the nine outer dense fibers are continuous with the same structures in the midpiece. A new flagellar accessory structure, the *fibrous sheath*, is the longest section of the sperm flagellum and closely underlies the plasma membrane. The fibrous sheath delineates the morphological boundaries of the principal piece and is characterized by circumferential ribs that bridge two longitudinal columns. The fibrous sheath can be considered as a tapering cylinder. The tips of the ribs thicken as they approach the longitudinal columns. This thickness decreases toward the end of the principal piece. The circumferential ribs end abruptly at the posterior margin of the principal piece where it transitions to the end piece (Fawcett, 1970, 1975). As mentioned above, outer dense fibers 3 and 8 are replaced by these columns in the principal piece. The longitudinal columns are 15–20 nm in diameter and formed by longitudinally positioned, loosely packed filamentous structures. The longitudinal columns run tangentially to and attach to ridges projecting from microtubule doublets 3 and 8 of the axoneme (Fawcett, 1970). In sperm with a falciform shape (mostly rodents species), the dorsal longitudinal column is closest to the microtubule outer doublet 3 while the ventral longitudinal column is closest to the microtubule outer doublet 8 (Fawcett, 1970). The fibrous sheath is an important structure of the sperm flagellum. It functions as a scaffold for glycolytic enzymes and proteins involved in signaling pathways that regulate sperm maturation, motility, capacitation, hyperactivation, and/or acrosomal exocytosis (Krisfalusi et al., 2006).

The plasma membrane of the principal piece differs in its composition compared to the midpiece. For example, components of the CATSPER calcium channel, which is required for male fertility, are restricted to the principal piece and are exquisitely structurally aligned with the longitudinal columns of the fibrous sheath. This, in addition to axoneme-driven motility, the principal piece of the sperm flagellum is significant for both metabolic reasons (compartmentalization of metabolic processes such as glycolysis) and cell signaling (specific protein kinases and ion channels).

End piece

The *end piece* of the sperm flagellum is the most distal segment. It contains no structural elements other than the axoneme (Fig. 3D). The end piece contains the axonemal doublets and begins where the outer dense fibers and fibrous sheath end. The plasma membrane of the end piece is contiguous with that of the principal piece.

Concluding Comments

The function of the spermatozoon is dictated by its structure. The complexity of this cell with its unique composition of proteins and organelles that are assembled in a temporally and spatially organized manner during spermiogenesis provides a challenging subject for study in the quest to understand the basis for male fertility.

Glossary

Chromatin DNA packaged by proteins. This is the way DNA molecules, which are much longer than the cell, that fit into the nucleus.

Epigenetics Heritable structures associated with chromatin that are not part of the DNA sequence. The most common forms of epigenetic modifications are DNA methylation and histone posttranslational modifications.

Histone A family of basic proteins that bind to DNA in most cells to form chromatin.

Nucleosomes The basic unit of somatic cell chromatin structure. One nucleosome contains two tetramers of histones each made up of one histone H1, H2A, H2B and H3, and about 200 bp of DNA coiled twice around the histones.

Protamine Very basic proteins that fold DNA into chromatin only in sperm cells.

Spermatozoa The male gamete. It is the final, mature form of the sperm cell that carries the father's DNA to the oocyte.

Somatic cell Any cell that is not a germ cell. The vast majority of cells in the body are somatic.

Introduction: The Complexity of the Problem

The sperm cell has the seemingly impossible task of packaging all the father's genes into a tiny compartment (the sperm nucleus) that must make a voyage that is equivalent to a person walking 1 (mouse) or 10 (human) miles to deliver that genetic information completely and utterly intact. The genes are encoded in 23 strands of DNA (in humans) that if stretched end to end is 1 m long, and is packaged into a tiny volume about 10 millionths of a meter (10 μm) long and half to 1 millionths of a meter (0.5–1.0 μm) wide. This is a difficult problem to visualize, and the best image is one that the distinguished professor at Johns Hopkins, Don Coffey, used to explain it with the now outdated technology of tape cassettes (Fig. 1). Tape cassettes organized long stretches of magnetized tape into a coils that the player could read. The tape had to be organized on the cassette's rollers for it to be functional. In somatic cells—the cells that make up our bodies—with the full complement of 46 chromosomes, 2 m of DNA must fit into a sphere about 10 μm in diameter—much larger than a sperm cell, but still relatively small. In both sperm and somatic cells, the DNA is coiled and

Fig. 1 Tape cassette as model for chromatin. All the tape has been pulled from the cassette and piled below it. The tape cassette is a good model for the folding the long strands of DNA into chromosomes. In both the tape cassette and the chromosome, the information-bearing strands, which are many orders of magnitude longer than the final compact package, must be ordered in a way that the information on the strands is accessible.

packaged by proteins into chromatin—complex units of DNA and protein that coil the long strands of DNA into functional units inside the cell. The major difference between the two is that in somatic cells the DNA must be available for all its normal functions—transcription of the 23,000 protein encoding genes and the million or so non-coding RNA genes, and DNA replication when the cell divides. The sperm cell, on the other hand, shuts down all DNA functions and can further compact the DNA. But, the sperm cell must deliver that DNA in a packaged form that can be easily opened, and, probably contains information about which genes to activate first, and where to start DNA replication. The sperm cell, like the oocyte, has the added burden of delivering a pristine copy of one parent's DNA to the oocyte to form the embryo, and, unlike the oocyte, to take that DNA on a long and hazardous journey protecting the DNA all the way.

There is a great deal we know about chromatin structure in sperm, but even more that we have yet to discover. In this article, we will explore both known aspects of sperm chromatin structure and the questions that remain.

Histone Based Chromatin (Most Cells and a Small Part of the Sperm Chromatin)

To understand sperm chromatin structure, we need a brief reminder about chromatin structure in most other cells. The 2 m of DNA is first coiled into nucleosomes by an octamer of proteins called histones ([Fig. 2B](#)). To coil DNA, the biggest problem is the negative charges that line both strands of the double helix because of the phosphates. These negative charges cause the DNA to repel from itself. The four human core histones are composed of 22%–25% basic amino acids (histidine, lysine and arginine) that have positive charges that can counter the negative charges of the DNA. This allows the histone octamers to wind about 200 bp of DNA twice around it to form nucleosomes, condensing the DNA strand into a “beads on a string”. Nucleosomes are usually depicted as short cylinders, but are, in fact, dimers of two short coils of four histones (H2A, H2B, H3 and H4) each connected together ([Luger et al., 1997](#)). They form a natural path for the DNA to coil twice around them. Note that the DNA is fairly accessible on at least one side, and many proteins are capable of binding to it in sequence-specific manners even in the nucleosome form. Nucleosomes are then compacted further ([Fig. 2C](#)) into what is called heterochromatin, a chromatin form that usually indicates genes that have been shut down. This packaging does not shorten the 2 m of DNA enough to fit inside the nucleus, however, and further packaging is required. To do this, the chromatin is organized into loop domains by a nuclear matrix ([Fig. 2D and E](#)). Thus, in somatic cells, the 2 m of DNA is compacted by histones and the nuclear matrix to fit inside the nucleus, but in a form that is still accessible for its functions.

Protamine Based Sperm Chromatin

During spermatogenesis, the chromatin of the precursor to the sperm cell, round spermatids, transforms its structure markedly from a typical histone-bound structure to a much more compact form. The proteins, called protamines, that form mammalian sperm chromatin are even more highly specialized to bind to DNA than histones. There are two types of protamines in humans called protamine 1 and protamine 2, and in their final form, they are composed of 57% and 67% basic amino acids, respectively. They bind to the DNA in the major groove ([Prieto et al., 1997](#)) essentially completely neutralizing the DNA ([Fig. 2G](#)). In sperm chromatin that is bound by protamines, there is virtually no access to the DNA double helix as there is in even the most compact forms of somatic chromatin (compare [Fig. 2D and I](#)). When all the charges are neutralized (and this can be accomplished either by protamines or divalent metals; [Hud and Downing, 2001](#)), DNA forms into tightly compact toroids ([Fig. 2I](#)). In the sperm cell, these toroids each contain 20,000–50,000 bp of DNA. The DNA was already almost completely inaccessible by its coating of tightly bound protamines ([Fig. 2G](#)), and with the formation of the toroid, most of the DNA is buried deep within the toroid, protected by surrounding DNA/protamine fibers. In this way the DNA is in an almost crystalline state, protected from damage by nucleases and mechanical stresses. One experiment is a particularly vivid illustration of how protected this sperm chromatin is. Even a brief sonication of somatic cells destroys them because the histone bound DNA does not prevent DNA double strand breaks. Mouse sperm, however, can be sonicated and then injected into oocytes to generate live pups ([Tatenio et al., 2000](#)). This demonstrates that all the sperm DNA survived the mechanical stress of the sonication. Protamines are uniquely evolved to compact that DNA about as tightly as it is possible for DNA to be packaged. They provide the protection needed to transport the father's DNA safely to the oocyte for productive fertilization.

In mammalian sperm chromatin, depending on the species, 1%–10% of the DNA remains bound to histones in fully mature sperm indicating that some of the sperm chromatin remains organized into nucleosomes rather than protamine toroids. An obvious question that has been asked is whether these histones are randomly placed or positioned on specific genes. Human sperm chromatin has a relatively large component of histone bound DNA, 10%, and several labs have provided evidence that the histones are positioned in at specific sites along the chromosome but they do not always agree on where these sites are ([Hammoud et al., 2009](#); [Brykczynska et al., 2010](#)). This specificity suggests that sperm DNA is packaged with functional consequences for development. For example, evidence from at least two laboratories suggests that some of the genes required for early development in the embryo are bound by histones in the sperm nucleus, suggesting that they are programmed by chromatin structure to activate shortly after fertilization ([Arpanahi et al., 2009](#); [Hammoud et al., 2009](#)).

Fig. 2 Comparison of somatic cell and sperm chromatin. (A–C) DNA in most cells is compacted by coiling around histone octamers. Note that the outside of the DNA is exposed, no matter how tightly the DNA is coiled by histones. (D–E) The chromatin is still relatively long, compared to the nucleus, and it is further collapsed by organizing into loops by the nuclear matrix. (F–I) In sperm, most of the DNA (90%–99%, depending on the species) is bound much more tightly by protamines that wrap around the DNA in the major groove. This protamine bound DNA folds into large toroids. (J) Some data suggests that each toroid is a loop domain. This figure is a modified version of a previously published figure in [Ward \(1993\)](#).

Higher Order Packaging in Sperm Chromatin

All the principles discussed above are fairly well established and accepted. But several important questions remain to be answered. One can predict, for example, that the 23 chromosomes are packaged into 30,000–60,000 protamine toroids which immediately begs the question of how these toroids are arranged in chromosome. We now enter the realm of predictive models for sperm chromatin structure that necessarily change as more data are accumulated. **Fig. 3** depicts our most current model for how the DNA is packaged in sperm chromatin based on several different lines of experiments, which are described in greater detail in this review

Fig. 3 Model for sperm chromatin structure. Protamine toroids are proposed to be stacked together, with nuclease sensitive linker regions of chromatin that also attach to the nuclear matrix. See text for details. A more complete description of this model can be found in [Ward \(2010\)](#).

([Ward, 2010](#)). There are two experimental results this model attempts to incorporate. First, even though it is packaged by protamines into impenetrable toroids, nuclease digestion of intact sperm nuclei result in the degradation of chromatin to 20–50 kb fragments ([Sotolongo et al., 2003](#)). Second, it is clear from different laboratories (reviewed in [Ward, 2010](#)) that sperm DNA is organized into loop domains similar to somatic cells (compare [Figs. 2E and J](#)). The fragments of DNA that are released by nucleases are within the range of predicted loop sizes, and it appears that each protamine toroid is equivalent to a single loop domain ([Sotolongo et al., 2003](#)). The most efficient way to package the toroids would be to stack them as shown in [Fig. 3](#) like a roll of life-saver candies. At least one laboratory has presented experimental evidence that this is the case ([Mudrak et al., 2009](#)). We have shown that the chromatin between the toroids is nuclease sensitive even though the DNA within the toroids is not ([Sotolongo et al., 2003](#)). Our model predicts that these toroid linker regions contain histone bound DNA, but there is no clear direct experimental evidence for that as of now. Our evidence also suggests that the toroid linker regions are the sites where the DNA loops attach to the sperm nuclear matrix. Beyond the predicted stacking of the toroids, there must also be further coiling to shorten the chromatin fibers to fit into the sperm cell. Any attempt to predict what that structure is would be pure speculation at this point.

We do have some idea, however, how the condensed chromosomes are arranged in the sperm nucleus. The telomeres of each chromosome appear to be attached to each other in at least six different mammalian species, and they are located towards the periphery of the sperm nucleus ([Zalensky et al., 1995, 1997](#)). The centromeres, on the other hand, coalesce together in the center of the nucleus. This results in a model for chromosome packaging in which the chromosome is bent in to a hairpin structure with the telomeres at the periphery and the centromeres at the center.

Functional Sperm Chromatin

Is there a function that the unique structure of sperm chromatin serves beyond protecting the DNA in the transit of the spermatozoon during fertilization? At least two different ideas have been proposed and the model for sperm packaging shown in [Fig. 3](#) suggests a structural focus for both functions.

The first proposed function is that the structure of the sperm chromatin functions in early embryogenesis. In other words, the overall role of the sperm is to not only deliver the intact paternal genome, but to provide instructions to the embryo on how to use that DNA. This is supported by several groups and has multiple levels of action. At least three levels of chromatin structure are thought to participate in embryogenesis and we have proposed a fourth. (i) DNA methylation is the clearest example. It has long been known that in a process called imprinting certain genes are methylated differently in paternal versus maternal DNA and that the correct methylation patterns on both are required for embryonic development ([Bartolomei and Tilghman, 1997](#)). This was the first evidence that something besides the genetic sequence of the DNA was inherited by the embryo from the gametes that was essential. As an extension of this, it is now clear that methylation of other genes may also be important for embryogenesis, even if they are methylated the same way on both gametes (ii) More recently, several laboratories have shown that the few histones that remain on the sperm genome are posttranslationally modified and that these modified histones are associated with specific genes ([Brykczynska et al., 2010](#)). This raises the possibility that these modified histones direct the embryo to focus on specific genes or chromosomal regions during early embryogenesis. (iii) It has recently been shown that sperm contain a host of paternal RNAs, the functions of which are only now being identified. Again, the possibility here is that these RNAs provide instructions to the

embryo on the proper use of the paternal genome. This model has gained considerable support with the recent discoveries of the importance of non-coding RNAs in gene regulation. (iv) Finally, we have proposed that the attachment sites of DNA to the nuclear matrix in the protamine toroid regions also provide information required for embryogenesis and have shown that these attachment sites are required for the replication of the paternal DNA in the embryo shortly after fertilization (Shaman et al., 2007). This suggests that the nuclear matrix attachment sites mark the origins of replication.

The proposed model in Fig. 3 suggests another possible function for sperm chromatin structure. The toroid linker regions are sensitive to nuclease digestion (Sotolongo et al., 2003), and we have shown that mammalian sperm can be induced to degrade its own DNA to loop-sized fragments in a process that we have termed sperm chromatin fragmentation (SCF) (Yamauchi et al., 2007). SCF mimics the DNA degradation of somatic cells in that the DNA is first reversibly fragmented by topoisomerase II, then irreversibly digested by nucleases (Li et al., 1999). SCF appears to occur on the nuclear matrix at the nuclease sensitive toroid linker regions. This suggests that when sperm DNA is compacted during spermiogenesis, the toroid linker regions remain accessible to topoisomerases and nucleases to allow the sperm cell to respond to external stimuli when necessary to initiate an apoptotic-like mechanism that incapacitates the sperm. The ability of spermatozoa to undergo apoptosis makes sense when one considers the millions of individual cells that invade the female uterus for each fertilization attempt. Most of these mobile carriers of foreign (to the female) DNA will not contribute to the production of progeny and must be destroyed. It has been argued that default status of spermatozoa is apoptosis and outside factors in the semen and uterus prevent it (Pujianto et al., 2010). The model for sperm chromatin structure presented in Fig. 3 illustrates how possible nuclease sensitive regions could allow the sperm cell to degrade its own DNA even while protecting 90%–99% of it as compact protamine bound toroids.

Summary

Mammalian sperm chromatin is the most densely packaged DNA known, yet it maintains windows of nuclease sensitivity that may also serve key functional roles in fertility and embryogenesis. Current models offer many hints as to how this highly condensed DNA can remain functional. We still have a long way to go before we understand just how the sperm is able to fold a meter of DNA inside its tiny volume.

Introduction

Male germ-cell development begins with the specification of primordial germ cells (PGCs), the common precursors for the spermatozoa and the oocytes, and culminates in the generation of spermatozoa that function to convey paternally derived genetic as well as epigenetic information to subsequent generations. The entire spermatogenesis process is one of the most complex cellular differentiation processes during mammalian development and physiology. In vitro spermatogenesis is a research discipline that aims at reconstituting the spermatogenesis processes in vitro, most ambitiously by means of pluripotent stem cells (PSCs) such as embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) as a starting material, and has been one of the most critical challenges in reproductive science (for review see Daley, 2007; Handel et al., 2014; Saitou and Miyauchi, 2016). If successful, it will represent a powerful strategy with which to study salient mechanisms underlying the whole spermatogenesis process, ranging from epigenetic reprogramming/programming to genetic stability to meiotic recombination (Baudat et al., 2013; Handel and Schimenti, 2010; Kong et al., 2012; Saitou et al., 2012), in a precise manner, and the resultant spermatozoa generated in vitro might serve as a critical resource for regenerative biology or medicine (e.g., see Hirota et al., 2017).

Much effort by numerous researchers has been dedicated toward this important objective, and as a result there have been a number of reports showing the induction of haploid spermatid-like cells from PSCs (see relevant references in Daley, 2007; Handel et al., 2014; Saitou and Miyauchi, 2016). However, most such reports have documented inductions with very low efficiency, which do not recapitulate the in vivo processes, and which somehow are not convincingly reproduced (Daley, 2007; Handel et al., 2014; Saitou and Miyauchi, 2016), leaving in vitro spermatogenesis as an unattained and formidable goal. On the other hand, during the last two decades, the methods for culturing rodent and human PSCs have become highly sophisticated (for review see Nichols and Smith, 2009), methods for culturing rodent spermatogonial stem cells (SSCs) have been established (Kanatsu-Shinohara et al., 2003; Kubota et al., 2004), and there have been solid advances in our understanding of the basic mechanisms underlying the entire spermatogenesis process (Griswold, 2016; Hermann et al., 2010; Saitou and Miyauchi, 2016). Accordingly, it has been demonstrated that mouse PSCs are induced into PGC-like cells (PGCLCs), which undergo spermatogenesis upon transplantation into neonatal mice lacking endogenous germ cells, and the resultant spermatozoa contribute to healthy offspring (Hayashi et al., 2011). It is also of note that an improved method for testis organ culture has been developed and has been used to differentiate and mature undifferentiated spermatogonia or a primary cell line bearing the SSC activity into haploid spermatids (Sato et al., 2011a,b). These advances heighten the prospect that the recapitulation of the entire process of spermatogenesis from PSCs may one day be possible. Indeed, remarkably, the entire mouse oogenesis process, the female counterpart of germ-cell development, has been reconstituted in vitro based on the PGC/PGCLC culture system (Hayashi et al., 2012; Hikabe et al., 2016; Morohaku et al., 2016). Here, we review the current state and ongoing progress of in vitro spermatogenesis studies, with an emphasis on those from mouse and human PSCs, and discuss future perspectives.

Male Germ-Cell Development and Spermatogenesis in Mice and Humans

Spermatogenesis begins with the specification of PGCs early during embryonic development (Fig. 1). In mice, a representative model organism for mammalian development, PGCs are induced within the most proximal posterior epiblast cells at around embryonic day (E) 6.0 in response to bone morphogenetic protein 4 (BMP4) and WNT3, and form a cluster of ~40 cells within the extra-embryonic mesoderm at around E7.25 (Ginsburg et al., 1990; Lawson and Hage, 1994; Ohinata et al., 2009; Saitou et al., 2002). The pluripotent epiblast cells bear competence for the germ cell fate from around E5.5 to E6.25 (Ohinata et al., 2009), and the transcription factors (TFs) essential for PGC specification include BLIMP1 (also known as PRDM1), PRDM14 and TFAP2C (also known as AP2γ) (Ohinata et al., 2005; Vincent et al., 2005; Weber et al., 2010; Yamaji et al., 2008). Upon specification, PGCs repress the somatic mesodermal program, re-acquire potential pluripotency, and embark on epigenetic reprogramming (for review see Saitou and Yamaji, 2012). Note that the epigenetic properties of PGCs at specification are similar to those of the epiblast cells and PGCs retain parental imprints inherited from spermatozoa and oocytes (Hajkova et al., 2002; Kagiwada et al., 2013; Seisenberger et al., 2012). PGCs initiate migration after around E7.25, move through the developing hindgut endoderm and mesentery, and colonize the incipient gonad primordium from around E10.5. During migration and colonization of the embryonic gonads, PGCs proliferate substantially (from ~40 cells at E7.25 to ~25,000 cells at E13.5) (Kagiwada et al., 2013; Tam and Snow, 1981), acquire the expression of key translational regulators DAZL (Cooke et al., 1996; Lin et al., 2008) and DDX4 (also known as mouse vasa homolog (mVH)) (Fujiwara et al., 1994; Tanaka et al., 2000), and importantly, undergo epigenetic reprogramming that includes genome-wide DNA demethylation, imprint erasure, and histone modification remodeling, thereby acquiring an epigenetic “blank slate” with equivalent epigenotypes for the paternal and maternal alleles (Hajkova et al., 2002; Popp et al., 2010; Seisenberger et al., 2012; Seki et al., 2005).

It is within the embryonic gonads that PGCs initiate their sexually dimorphic development (Fig. 1). In embryonic ovaries, in response to cues from ovarian somatic cells, from around E13.5, PGCs progress toward the oogenic pathway and enter into the

Fig. 1 Male germ-cell development and spermatogenesis in mice and humans. Scheme showing the key cell types and events during male-germ cell development and spermatogenesis in mice (top) and humans (bottom). The color code of the key events is shown on the top. PGCs, primordial germ cells; SSCs, spermatogonial stem cells; As, A single; Apr, A paired; Aal, A aligned.

prophase of meiosis I, heralding the oocyte development (see [Edson et al., 2009](#); [McGee and Hsueh, 2000](#) for further details on oocyte development). In contrast, in embryonic testes, in response to signals from or environments created by embryonic testicular somatic cells, from around E13.5, PGCs cease their cell cycle (mitotic arrest) and differentiate into pro-spermatogonia or gonocytes (for review see [Manku and Culty, 2015](#); [Spiller et al., 2017](#)). The mechanism that drives the differentiation of PGCs into the male pathway remains obscure, but the signaling pathways involving nodal, prostaglandin D2, and fibroblast growth factor 9 (FGF9) appear to play key roles ([Manku and Culty, 2015](#); [Spiller et al., 2017](#)), and the translational regulator NANOS2 integrates the system that represses the female pathway and promotes the male differentiation ([Suzuki and Saga, 2008](#); [Tsuda et al., 2003](#)). Located within the luminal side of the testicular cords (primitive seminiferous tubules) created by embryonic Sertoli cells, the pro-spermatogonia continue to be mitotically arrested until after birth and gradually establish the properties of spermatogonia, including the expression of a key TF, PLZF (also known as ZBTB16), and of receptors for the key mitogen of SSCs, glial-cell-derived neurotrophic factor (GDNF) ([Meng et al., 2000](#)), GFR α 1 and RET ([Griswold, 2016](#); [Hermann et al., 2010](#); [Manku and Culty, 2015](#)). The key event that takes place during this period is the establishment of the androgenetic epigenome including paternal imprints ([Kubo et al., 2015](#); [Seisenberger et al., 2012](#)), which requires de novo DNA methyltransferases (DNMT) 3A and 3L and the machinery for PIWI-interacting RNA (piRNA) biogenesis, such as PIWIL2 (also known as MILI), PIWIL4 (also known as MIWI2), and Tudor domain-containing proteins (TDRDs) (for review see [Chuma and Nakano, 2013](#); [Siomi et al., 2011](#)).

From at around postnatal day (P) 3, the pro-spermatogonia translocate to the basal compartment of the seminiferous tubules, differentiate into spermatogonia by an unknown mechanism, and resume mitotic proliferation ([Griswold, 2016](#); [Hermann et al., 2010](#); [Manku and Culty, 2015](#); [Fig. 1](#)). Some of the spermatogonia in turn proceed directly to spermatogenesis by entering into meiosis, and produce spermatozoa by 4 weeks after birth (first-wave spermatogenesis) ([Bellve et al., 1977](#); [Yoshida et al., 2006](#)). On the other hand, some spermatogonia are recruited into SSCs, which, with their remarkable capacity for self-renewal and spermatogenic differentiation, support the spermatogenesis throughout the life of individual animals ([Griswold, 2016](#); [Hermann et al., 2010](#); [Yoshida, 2016](#)). The identity of SSCs has long been debated: one idea posits that A single (As) spermatogonia or a subpopulation of As spermatogonia are the only bona fide SSCs that can self-renew and support the life-long spermatogenesis, whereas another proposal submits that a collective pool of cells expressing GFR α 1, including As, A paired (Apr), and A aligned (Aal), can function as SSCs (for review see [de Rooij, 2017](#); [Griswold, 2016](#); [Hermann et al., 2010](#); [Yoshida, 2016](#)). The TFs such as PLZF, and signaling molecules such as GDNF, FGFs, and WNTs ensure the self-renewal of SSCs, and the TFs such as SOHLH1/2 and STRA8, and signaling molecules such as retinoic acid (RA) and stem cell factor (SCF) are critical for SSCs to enter into meiosis ([de Rooij, 2017](#); [Griswold, 2016](#); [Hermann et al., 2010](#); [Yoshida, 2016](#)). Upon entry into meiotic divisions, spermatogonia translocate to the luminal compartment of the seminiferous tubules to differentiate into spermatocytes, which upon completion of meiosis, differentiate into spermatids and then into mature spermatozoa to acquire the characteristic sperm morphology with protamine-based compact chromatin (spermiogenesis) (for review see [Kimmins and Sassone-Corsi, 2005](#)). It is critical to note that the luminal compartment of the seminiferous tubules represents a distinct fluid and hormonal milieu established by the tight junctions of the Sertoli cells (blood-testis barrier) ([Russell et al., 1990](#); [Yoshida, 2016](#)). It takes approximately ~35 days for differentiating spermatogonia to form mature spermatozoa, with ~14 days for the completion of meiosis I ([Griswold, 2016](#); [Hermann et al., 2010](#)).

In humans, male germ-cell development and spermatogenesis take a pathway generally similar to that in mice, but require a much longer time, appear to involve substantial developmental heterogeneity/asynchronicity, and exploit molecular mechanisms divergent from those in mice (for review see [Hermann et al., 2010](#); [Manku and Culty, 2015](#); [Saitou and Miyauchi, 2016](#); [Tang et al., 2016](#); [Fig. 1](#)). Human PGCs (hPGCs) are specified presumably at around week 2 (Wk2) of development via an unknown mechanism. Notably, it has been shown that in cynomolgus monkeys, PGCs are specified as early as E11 in the nascent amnion segregated from the epiblast upon implantation ([Sasaki et al., 2016](#)), suggesting that hPGCs are also specified in the amnion. hPGCs undergo migration similarly to mouse PGCs and colonize the anlage of embryonic testes from around Wk5 ([De Felici, 2013](#); [Witschi, 1948](#)). hPGCs continue to proliferate at least until Wk10–12 in embryonic testes, and thereafter gradually enter into mitotic arrest in an asynchronous fashion to differentiate into pro-spermatogonia ([Culty, 2009](#)). The number of hPGCs is around ~100 at Wk3, which increases to around ~1000 at Wk4 and to around ~150,000 at Wk9 ([De Felici, 2013](#); [Mamsen et al., 2011](#)), and during this period, hPGCs undergo the epigenetic reprogramming, acquiring an epigenetic blank slate ([Gkoutela et al., 2015](#); [Guo et al., 2015](#); [Tang et al., 2015](#)).

Some of the pro-spermatogonia translocate to the basal compartment of the seminiferous tubules and differentiate into spermatogonia during the embryonic period ([Culty, 2009](#); [Fig. 1](#)). After birth, human spermatogonia population appears to be maintained in a dynamic balance for more than a decade until the onset of puberty ([Paniagua and Nistal, 1984](#)), after which they undergo spermatogenesis and SSCs continue to provide spermatogenesis throughout the lifetime of the individual. It takes ~64 days for differentiating human spermatogonia to form mature spermatozoa, with ~23 days for the completion of meiosis I ([Griswold, 2016](#); [Hermann et al., 2010](#); [Yoshida, 2016](#)). Obviously, our knowledge of the mechanisms of human germ-cell development and spermatogenesis is limited, apart from the information obtained from classical morphological observations. The recent development of many key technologies, including those that allow massively parallel transcriptome analyses from single cells, is expected to provide valuable insights into the mechanisms of human germ-cell development ([Guo et al., 2015](#); [Li et al., 2017](#)), for which obtaining sufficient experimental materials is often difficult.

Male Germ-Cell Development and Spermatogenesis From Mouse PSCs

Based on the current knowledge of male germ-cell development and spermatogenesis, and on relevant reproductive technologies—most prominently, the SSC transplantation assays ([Brinster and Avarbock, 1994](#); [Brinster and Zimmermann, 1994](#); [Fig. 2](#))—these processes are beginning to be reconstituted step-by-step using mouse PSCs as a starting material ([Saitou and Miyauchi, 2016](#)). As a first step in this process, mouse PSCs were induced by activin A and bFGF into epiblast-like cells (EpiLCs), which were in turn induced essentially by BMP4 into PGC-like cells (PGCLCs) in floating aggregates ([Hayashi et al., 2011](#); [Fig. 3](#)). Gene-expression dynamics during the induction of mPSCs to EpiLCs to PGCLCs recapitulated those during progression from the E4.5 epiblast to E6.0 epiblast to PGC specification, and EpiLCs and PGCLCs induced for 4–6 days (d4/d6 PGCLCs) exhibited gene-expression properties similar to those of the E6.0 epiblast and E9.5 PGCs, respectively ([Hayashi et al., 2011](#)). Remarkably, like PGCs ([Chuma et al., 2005](#)) and those induced from the epiblast *ex vivo* ([Ohinata et al., 2009](#)), when PGCLCs were transplanted into the testes of neonatal mice lacking endogenous germ cells (*W/W^u* mice bearing mutations in *KIT*), they successfully reconstituted spermatogenic colonies and differentiated into spermatozoa, and the resultant spermatozoa robustly contributed to apparently healthy offspring ([Hayashi et al., 2011](#)). These findings represent the first demonstration that mPSCs can differentiate *in vitro* into germline cells with an appropriate function. Subsequently, it was shown that when aggregated with embryonic ovarian somatic cells and transplanted under the ovarian bursa of immune-deficient mice, female PGCLCs are differentiated and matured into oocytes at the germinal vesicle stage, and the resultant oocytes contribute to healthy offspring following *in vitro* maturation (IVM) and fertilization (IVF) ([Hayashi et al., 2012](#)). Thus, mouse PGCLCs function as precursors both for the spermatozoa and the oocytes and are considered as a bona fide *in vitro* counterpart of PGCs.

Accordingly, the system for PGCLC induction has been exploited for the identification of TFs sufficient for conferring the germ-cell fate ([Nakaki et al., 2013](#)), for clarifying a detailed signaling and transcriptional cascade leading to PGC specification ([Aramaki et al., 2013](#)), and for delineating the histone modification remodeling and DNA methylation reprogramming associated with PGC specification ([Kurimoto et al., 2015](#); [Shirane et al., 2016](#); [von Meyenn et al., 2016](#)). Importantly, the latter studies ([Kurimoto et al., 2015](#); [Shirane et al., 2016](#); [von Meyenn et al., 2016](#)), together with other studies on PGCs *in vivo* ([Arand et al., 2015](#); [Kagiwada et al., 2013](#); [Seisenberger et al., 2012](#)), have clarified that genome-wide DNA demethylation in PGC(LC)s occurs in a manner consistent with a replication-coupled passive dilution having differing dilution rates for single-copy sequences (unique regions), distinct regulatory elements, and repeats. This appears to be achieved through the repression of key components of the *de novo* as well as the maintenance DNA methyltransferase machineries (DNMT3A/B and UHRF1) upon PGC(LC) specification by BLIMP1/PRDM14/TFAP2C ([Kagiwada et al., 2013](#); [Kurimoto et al., 2008, 2015](#); [Seisenberger et al., 2012](#); [Seki et al., 2005](#); [Shirane et al., 2016](#)). Consequently, the genome-wide DNA methylation profiles of PGCs/PGCLCs show a diluted configuration of those of epiblast/EpiLCs, and d6 PGCLCs bear ~40% of genome-wide 5mC levels ([Shirane et al., 2016](#)).

A more recent study has attempted an induction of SSCs from PGCLCs *in vitro* ([Ishikura et al., 2016](#); [Fig. 3](#)). d4 PGCLCs were aggregated with somatic cells of E12.5 embryonic testes and were cultured on a Trans-well system under an air-liquid interface culture condition. Under this condition, the aggregates formed an embryonic testis-like structure with reconstituted seminiferous tubules maintaining the expression of GATA4 and SOX9, key TFs for Sertoli cells ([Vidal et al., 2001](#); [Viger et al., 1998](#)). Within these structures (reconstituted testes), PGCLCs survived preferentially inside the seminiferous tubules, increased in number, and

Fig. 2 Germ-cell transplantation assays. (A) Scheme showing the germ-cell transplantation assay. Donor germ cells are transplanted into the rete testis of germ-cell depleted mice (mice treated with busulfan or *W/W^u* mice) and their colonization and spermatogenesis are examined 2–3 months after the transplantation. The photograph on the right shows a section of the transplanted testis with seminiferous tubules showing spermatogenesis (arrowhead) or no spermatogenesis (*: un-colonized tubules). The section was stained by hematoxylin and eosin. (B) Scheme showing donor cell types (top: cells *in vivo*; bottom: cells *in vitro*) and recipients used for germ-cell transplantation assays in mice. ⊙: Colonization and spermatogenesis with high efficiency; ○: colonization and spermatogenesis with low efficiency; –: no colonization. Key references are shown.

up-regulated DDX4, a key marker for gonadal PGCs (Fujiwara et al., 1994; Tanaka et al., 2000), from around 10 days of the culture; in addition, a subset of the DDX4-positive cells up-regulated PLZF, an SSC marker that initiates expression perinatally in pro-spermatogonia (Buas et al., 2004; Costoya et al., 2004), from around 20 days of culture. Thereafter, the cultures of the reconstituted testes were maintained up to ~2 months at 34°C, a permissive temperature for spermatogenic meiosis (Sato et al., 2011a; Steinberger et al., 1964), and a few PGCLC-derived cells became positive for SCP3, a marker for the onset of meiosis (Yuan et al., 2000), but no cells completed meiosis under the reported condition (Ishikura et al., 2016). These findings indicate that PGCLCs differentiate at least up to spermatogonia-like cells in the reconstituted testes *in vitro*, although their differentiation kinetics is protracted compared to that of PGCs *in vivo* (Fig. 3).

It has been well-established that mouse SSCs can be propagated *in vitro* in the presence of cytokines including GDNF as germline stem cells (GSCs) (Kanatsu-Shinohara et al., 2003; Kubota et al., 2004). Upon transplantation into either neonatal or adult mouse

Fig. 3 Reconstitution of male germ-cell development in vitro and ex vivo. (A) Scheme showing the current state of in vitro (focused on the experiments recapitulating the in vivo processes) and ex vivo reconstitution of male germ-cell development and spermatogenesis in mice. Key cell types and gene expression during male germ-cell development are shown at the bottom. Reconstitution pathways involving cytokines and chemicals, reconstituted testes culture, ex vivo testes culture, and transplantation into seminiferous tubules, are shown. **Black bold arrows**, the induction steps reported; **gray bold arrows**, the induction steps necessary to be established; **blue arrows**, transplantation; **blue dotted arrow**, transplantation necessary to be performed. See text for details and key references. (B) Scheme showing in vitro reconstitution of germ-cell development in humans. See text for details and key references.

testes depleted of endogenous germ cells, GSCs colonize the testes to form spermatogenic colonies, and the resultant spermatozoa contribute to healthy offspring (Kanatsu-Shinohara et al., 2003; Kubota et al., 2004). It is important to note that while PGCs/PGCLCs colonize and undergo spermatogenesis only in testes of neonatal mice, SSCs/GSCs do so in testes of both neonatal and adult mice, and the male germ cells acquire the capacity to colonize/undergo spermatogenesis in adult testes upon their differentiation into pro-spermatogonia (after ~E14.5) (Chuma et al., 2005; Ohta et al., 2004; Shinohara et al., 2001; Fig. 2). Thus, GSCs are a primary cell line that is enriched with cells bearing the SSC activity, although their cellular heterogeneity remains

to be fully elucidated (Kanatsu-Shinohara and Shinohara, 2013). Accordingly, spermatogonia-like cells derived from PGCLCs in the reconstituted testes were propagated as GSC-like cells (GSCLCs) under the GSC culture condition (Ishikura et al., 2016). GSCLCs exhibited a morphology, proliferation kinetics, surface-marker expression, and expression of key genes highly similar to those of GSCs. Remarkably, unlike PGCLCs, GSCLCs colonized adult testes robustly upon transplantation. However, it was found that only a few GSCLC lines (3 out of 15 examined) underwent spermatogenesis in a fraction of colonized tubules, and a majority of colonized cells halted the spermatogenesis at around the entry into or early stages of the first meiotic prophase. Nonetheless, spermatozoa derived from GSCLCs were retrieved consistently and contributed to healthy offspring. Thus, PGCLCs can be induced into the male pathway to form spermatogonia-like cells in vitro, which can be propagated as a stable cell line with the SSC activity (Fig. 3).

Compared to GSCs, the capacity of GSCLCs for spermatogenesis was found to be limited. Transcriptome and genome-wide DNA methylome analyses revealed that GSCLCs bear global transcription and DNA methylation profiles similar to GSCs and to P7 KIT-negative undifferentiated spermatogonia, but in promoters and non-promoter CpG islands, GSCLCs exhibited 5mC levels consistently higher than such cell types (Ishikura et al., 2016). The hyper-methylated promoters in GSCLCs constituted ~3.0%–5.0% of all promoters and the associated genes exhibited a tendency to be repressed and included key genes for spermatogenesis, such as *Pou5f1*, *Sohlh1*, *Dpep3*, *Spo11*, *Tex19.1*, *Tdrd9*, and *Piwi1*. GSCLCs also exhibited aberrant methylation profiles of some of the differentially methylated regions (DMRs) of maternally imprinted genes. Investigation of the methylation-level dynamics of the hyper-methylated promoters during male germ-cell development in vivo revealed that the hyper-methylation of these promoters can be a combinatorial consequence of an incomplete DNA demethylation during reprogramming and aberrant DNA methylation during androgenetic programming (Ishikura et al., 2016). Thus, an improvement of culture conditions for reconstituted testes to prevent the hyper-methylation of these promoters, e.g., by using an appropriate index for epigenetic reprogramming/androgenetic programming, or separate culture for PGCLCs for the completion of genome-wide DNA demethylation followed by reconstituted testis culture, will lead to an induction of spermatogonia-like cells and GSCLCs with better function.

It was reported that d6 mPGCLCs enter into the prophase of meiosis I during the first 6 days when co-cultured with dissociated testicular cells of neonatal W/W^m mice in the presence of retinoic acid (RA), BMP2/4/7, and activin A, and such cells complete meiosis over the following 8 days when follicle stimulating hormone (FSH), bovine pituitary extract (BPE), and testosterone are provided, resulting in the generation of spermatid-like cells that contribute to healthy offspring (Zhou et al., 2016). This is a surprising result, because the reported procedure skips a period of male germ-cell development necessary for completing the epigenetic reprogramming, acquiring the androgenetic epigenome and differentiating into spermatogonia (more than 2 weeks of development in vivo—i.e., the period from PGCs at around E9.5 (d6 PGCLCs) to spermatogonia initiating the first wave spermatogenesis at around P10), and also because the culture was conducted at 37°C, a non-permissive temperature for spermatogenesis (Sato et al., 2011a; Steinberger et al., 1964). Hence, we consider that the validity of this study, including a more precise analysis of the induced intermediate cell types, warrants re-examination.

On the other hand, it has recently been shown that mouse d4 PGCLCs can be expanded up to ~50 fold on a sub-line of m220 feeders in the presence of SCF, forskolin and rolipram, the latter two of which elevate cAMP levels in PGCLCs (Ohta et al., 2017; Fig. 3). The PGCLCs essentially maintain their transcriptome as migrating PGCs during the expansion culture, but remarkably, consistent with the notion that genome-wide DNA demethylation in PGCs proceeds predominantly through replication-coupled passive dilution, the PGCLCs progressively erase their genome-wide DNA methylation, resulting in genome-wide 5mC levels of ~20% and ~6% at culture day 3 (d4c3) and 7 (d4c7), respectively (Ohta et al., 2017). Importantly, the 5mC distribution patterns in all genomic regions, including single-copy sequences (unique regions), repeats and the DMR of imprinted genes, of d4c3 and d4c7 PGCLCs were essentially identical to those of E10.5 PGCs and E13.5 male/female germ cells, respectively (Ohta et al., 2017). This work demonstrates that the genome-wide DNA demethylation and sexual differentiation of germ cells that occur in embryonic gonads by E13.5 are controlled by distinct genetic mechanisms, providing a potentially ideal starting material for the in vitro sex differentiation of germ cells and the reconstituted testis culture. Accordingly, a recent study has demonstrated that in response to BMP and RA, cultured PGCLCs can be induced into embryonic primary oocytes, and initiate and progress the prophase of meiosis I up to the pachytene stage (Miyauchi et al., 2017). It would be an interesting subject for future research to identify a defined condition—i.e., cytokines or compounds—to induce the male germ-cell fate in cultured PGCLCs without the use of testicular somatic cells.

It is critical to point out that recent years have also seen significant progress in the methodologies for the ex vivo organ culture of mouse testes, allowing the differentiation and maturation of undifferentiated spermatogonia into haploid spermatids with the capacity for contributing to healthy offspring (Sato et al., 2011a; Fig. 3). In these experiments, neonatal mouse testes that contain undifferentiated spermatogonia, but not their differentiated progeny, were isolated and their fragments preserving the organization of seminiferous tubules were placed on an agarose gel and cultured under an air-liquid interface condition at 34°C in the presence of knockout serum replacement (KSR), and the spermatogonia successfully underwent meiosis and formed haploid spermatids. Importantly, this system was extended to differentiate mouse GSCs into spermatids: GSCs were transplanted into neonatal W/W^m mouse testes and their fragments were cultured ex vivo, resulting in the generation of GSC-derived spermatids and healthy offspring (Sato et al., 2011b). More recently, a system to culture testicular fragments on a microfluidics apparatus was developed, allowing a constant, periodical production of spermatids from spermatogonia over more than 6 months (Komeya et al., 2016). Currently, with this ex vivo culture system, spermatids can be generated even from embryonic testes after E14.5, but not from those in earlier stages (Kojima et al., 2016). It would be an interesting line of research to combine the induction of GSCLCs from PSCs and their differentiation in the ex vivo culture system.

Germ-Cell Development From Human PSCs

Based on the system for the in vitro germ-cell development from mouse PSCs, human germ-cell development has begun to be reconstituted from human PSCs (Fig. 3). In one method, hESCs/hiPSCs maintained under a distinct condition with four kinase inhibitors (4i) (Gafni et al., 2013) were induced into human PGCLCs by BMP4 (Irie et al., 2015; Kobayashi et al., 2017), whereas in another, hiPSCs cultured under a conventional condition (Nakagawa et al., 2014) were first induced by activin A and WNT signaling into incipient mesoderm-like cells (iMeLCs) expressing genes such as *T*, *MIXL1*, and *EOMES*, which were in turn induced into hPGCLCs by BMP4 (Sasaki et al., 2015; Yokobayashi et al., 2017). hPGCLCs bear a property similar to human and cynomolgus monkey PGCs just after specification and do not yet up-regulate genes such as *DAZL* and *DDX4* (Irie et al., 2015; Sasaki et al., 2015, 2016). hPSCs cultured with 4i exhibited expression of some mesodermal genes and showed some of the properties of gastrulating cells, and were thus likely to exist in a state similar to iMeLCs (Sasaki et al., 2015). hPSCs cultured under conventional conditions bear a property similar to the post-implantation epiblast of cynomolgus monkeys, a primate model closely related to humans (Nakamura et al., 2016), and the PGCLC induction efficiency among multiple hiPSC lines has been correlated with the expression levels of genes such as *T*, *MIXL1*, and *EOMES* (Yokobayashi et al., 2017).

Importantly, using these in vitro systems, it has been shown that the mechanism for hPGC specification likely involves signaling and transcriptional mechanisms distinct from those in mouse PGC specification (Irie et al., 2015; Kobayashi et al., 2017; Kojima et al., 2017; Sasaki et al., 2015; Yokobayashi et al., 2017). In response to WNT signaling, *EOMES*, but not *T*, activates *SOX17*, and *SOX17* and *TFAP2C* establish the hPGC program, including *BLIMP1* expression, in an interdependent fashion (Kojima et al., 2017). Thus, key TFs themselves as well as their hierarchy of actions are different between human and mouse PGC specification.

At present, in vitro reconstitution of human germ-cell development from hPSCs is in its incipience and should be conducted in a step-by-step manner, based on the concepts and reconstitution procedures established in mice, as well as in part on the knowledge obtained from appropriate primate models, such as the fact that primate PGCs are specified in the amnion (Sasaki et al., 2016). It may also be important to take much longer developmental times for human germ-cell development into consideration. We consider that a key next step would be to explore the methodologies to induce epigenetic reprogramming and sex determination in hPGCLCs. The development of a method to propagate human SSCs in vitro is also a salient challenge.

Perspective

The last decade has seen significant progress in the in vitro reconstitution of germ-cell development in mice. Indeed, the entire female germ-cell development and the male germ-cell development up to the differentiation of spermatogonia/SSCs reflecting the in vivo germ-cell development have been reconstituted using mouse PSCs as starting materials (Hikabe et al., 2016; Ishikura et al., 2016). The key to the reconstitution of the entire spermatogenesis process in vitro is to realize the trans-meiotic differentiation of spermatogonia into spermatids, which has been pursued for many years, but appears to remain elusive, although one report claims to have gone through this process using a relatively simple methodology (Zhou et al., 2016). This goal will perhaps require a better understanding and the reconstitution of the intra-luminal environment of seminiferous tubules generated by the Sertoli cells, within which spermatogenic meiosis progresses. Toward this goal, efforts using GSCs as a starting material would be critical (Wang et al., 2016). At the same time, considering the key roles played by Sertoli cells and other testicular somatic cells in spermatogenesis (Russell et al., 1990), investigation into their development and their induction from PSCs would be a promising field of research. On the other hand, in vitro reconstitution of human germ-cell development and gametogenesis is an emerging challenge with many exciting potential applications (Saitou and Miyauchi, 2016; Tang et al., 2016). Given the much longer times required for human germ-cell development and the ethical and social impacts of the realization of human in vitro gametogenesis, such studies will require much persistent and careful effort (Ishii and Saitou, 2017).

Acknowledgments

We thank the members of our laboratory for their discussion of this study. This work was supported in part by a Grant-in-Aid for Research Activity Start-up from JSPS (17H06802) to Y.I., a Grant-in-Aid for Specially Promoted Research from JSPS (17H06098) to M.S., and by a grant from JST-ERATO (JPMJER1104) to M.S.

OOGENESIS

Growth and Meiotic Maturation of Mammalian Oocytes: An Overview

Hugh J Clarke, McGill University, Montreal, QC, Canada; and McGill University Health Centre, Montreal, QC, Canada

© 2018 Elsevier Inc. All rights reserved.

Introduction

A newborn girl carries up to about a million germ cells, known as oocytes, each housed in a structure termed a primordial follicle (Kerr et al., 2013). The weight of current evidence indicates that female mammals do not generate new oocytes after birth—in contrast to the continuous production of new sperm by sexually mature males—meaning that the endowment of oocytes that a female receives at birth represents her lifetime supply. The generation of oocytes and their prenatal differentiation and assembly into follicles has been recently reviewed and will not be discussed here (Jorgensen, 2013; Pepling, 2012). Postnatal development of the oocyte can be divided into two phases—growth, which is a slow process that requires 3–4 months in humans, and meiotic maturation, a much more rapid process that occurs at the time of ovulation and requires about 36 h in humans (Fig. 1). During

Fig. 1 Growth and meiotic maturation of the oocyte. Upper: Growth of the oocyte and its follicle are coordinated as shown. Entry into growth is marked by a transition of the granulosa cells from a squamous to a cuboidal morphology and an increase in the size of the oocyte. As the oocyte continues to grow, the granulosa cells proliferate, generating multiple layers. The elaboration of the zona pellucida, an extracellular coat assembled from oocyte-secreted glycoproteins, physically separates the oocyte from the bodies of the granulosa cells. At the secondary follicle stage, thecal cells come to lie external to the granulosa cells, from which they are separated by a basement membrane. Near the time that the oocyte reaches full-size, a fluid-filled cavity termed the antrum appears in the follicle, separating the granulosa cells into mural and cumulus subpopulations. The chromatin of fully grown oocytes becomes partially condensed around the nucleolus-like body; this process is termed the NSN-to-SN transition and is associated with transcriptional arrest. Growing oocytes accumulate large reserves of mRNAs, some of which are stored for future translation, and organelles including mitochondria. Lower: During meiotic maturation, the oocyte enters M-phase of the cell cycle. The membrane surrounding the germinal vesicle (nucleus) breaks down, and the chromosomes condense and become aligned on a spindle. Following translocation of the spindle to the oocyte cortex, the first meiotic division occurs such that one set of homologous chromosomes is discarded in the small first polar body. The oocyte advances to metaphase II where it becomes arrested until fertilization triggers completion of the second meiotic division. Numerous cytoplasmic changes that are not shown, including translational activation of previously silent mRNAs, also occur during maturation. As the oocyte matures, the cumulus granulosa cells secrete a gelatinous matrix that pushes them away from the oocyte and from each other, thus terminating physical contact between the two cell types.

growth and maturation of the oocyte, the follicle also undergoes dramatic and coordinated changes, and so these are discussed together below.

Growth

In order to maintain a stock of oocytes throughout reproductive life, the entry of oocytes within primordial follicles into the growth phase must be strictly regulated. We do not know what controls the rate or number of primordial follicles that begin to grow—why one or several primordial follicle may begin to grow whereas their neighbors does not. It is intriguing, however, that when follicles are aggregated together to generate an ovary-like structure, all begin to grow at the same time (Hayashi et al., 2012; Eppig and Wigglesworth, 2000). This suggest that the mechanisms that regulate entry of follicles into the growth phase are embedded in the architecture of the intact ovary.

The first indication that an oocyte within a primordial follicle has begun to grow is an increase in the diameter of the oocyte and a morphological transition of the somatic granulosa cells that surround the oocyte from a squamous to a cuboidal shape (Fig. 2) (Mora et al., 2012; Eppig et al., 2000). Since both cell types manifest changes at approximately the same time, which one is responsible for the initiating signal? Evidence so far points to the granulosa cells (Saaticioglu et al., 2016; Zhang et al., 2014). The granulosa cells are known to produce Kit ligand (KITL) while oocytes express its receptor KIT. Activation of KIT by its ligand in other cell types activates the phosphatidylinositol 3-kinase (PI3K) signaling pathway, which in turn leads to an increase in protein synthesis, and recent studies indicate that an increase in KITL production by the granulosa cells triggers oocyte growth through this mechanism. Through the use of appropriate genetic mutations, however, it is possible to experimentally activate KIT signaling in the oocyte in a ligand-independent manner. In this case, the oocyte begins to grow, but the granulosa cells remain squamous. This result suggests that oocyte growth per se does not trigger the squamous-cuboidal transition of the granulosa cells, favoring the idea that the signal for entry of the primordial follicle into the growth phase originates in the granulosa cells. Nonetheless, the question is not entirely resolved. We still do not know what causes the granulosa cells to increase production of KITL, and it is conceivable that this occurs in response to a signal from the oocyte.

Entry into the growth phase is accompanied by major changes in the pattern of gene expression in the oocyte. Although mechanistic links remain to be established, this genetic reprogramming probably plays a key role in driving oocyte growth. FOXO3 is predominantly nuclear in oocytes in primordial follicles, but translocates to the cytoplasm shortly after initiation of oocyte growth, and genetic deletion of *Foxo3* causes most oocytes in primordial follicles to begin to grow (Castrillon et al., 2003). Similarly, deletion of the oocyte-specific transcription factor *Sohlh2* (Choi et al., 2008) or oocyte-specific deletion of transcription factor *Lhx8* (Ren et al., 2015) also trigger initiation of oocyte growth, apparently independently of signals from the granulosa cells. These changes in transcription factor activity seem likely to represent part of the mechanism that responds to the growth-promoting signals sent by the granulosa cells.

Once oocyte growth has been initiated, it continues in an apparently continuous manner until the oocyte reaches a species-specific size—for example, approximately 120 μm in humans and 75 μm in mouse. This represents an increase of 100- to 200-fold in volume as compared to an oocyte in a primordial follicle. Whether growth requires continuous “activating” signals from the granulosa cells is not clear; however, KITL and KIT continue to be expressed by granulosa cells and growing oocyte, respectively, and KITL can stimulate continued growth of partially grown oocytes in vitro (Kidder and Vanderhyden, 2010). What is certain,

Fig. 2 Initiation of growth. Oocytes in primordial follicles are enclosed by a layer of squamous granulosa cells. Unknown signals induce the granulosa cells to assume a cuboidal morphology and probably also to increase synthesis of KITL. This ligand binds to its receptor, KIT, on the oocyte surface leading to activation of the PI3-kinase signaling pathway. This in turn increases protein synthesis in the oocyte, which begins to grow. Activating PI3-kinase signaling in the oocyte can trigger its growth even when the granulosa cells remain squamous.

however, is that the granulosa cells play an indispensable role. This has been shown in two ways. First, when partially grown oocytes enclosed by granulosa cells are removed from the follicle and placed in culture, they will continue to grow, whereas such oocytes from which the granulosa cells have been removed will not. Second, an extensive network of gap junctions couples the oocyte to adjacent granulosa cells, as well as the granulosa cells to each other. When either oocyte–granulosa cell or granulosa–granulosa cell gap junction coupling is disrupted by mutation of genes encoding their constituent proteins, oocytes fail to grow to full-size and are unable to develop as embryos (El-Hayek and Clarke, 2016; Winterhager and Kidder, 2015). These results demonstrate that the granulosa cells provide essential products to the oocytes via gap junctions and that disrupting granulosa cell interactions impairs their ability to supply these products. It is noteworthy that there is partial, albeit limited, oocyte growth when gap junctional coupling with the granulosa cells is abolished, but no oocyte growth when the granulosa cells are physically separated from the oocyte. This implies that oocyte growth requires an additional contact-dependent interaction with the granulosa cells—possibly the KIT-KIT signaling described above.

Several essential products provided to oocytes by the granulosa cells have been identified (Fig. 3) (Su et al., 2009). Oocytes express only low levels of mRNAs encoding enzymes required to metabolize glucose to pyruvate that acts as a source of ATP, whereas these mRNAs are expressed much higher levels in the granulosa cells. Consistent with these observations, pyruvate produced in the granulosa cells is transferred to the oocyte. Oocytes also take up certain amino acids poorly, which are transferred to them from the granulosa cells via the gap junctions. Finally, cholesterol produced by the granulosa cells is transferred to the oocyte. Granulosa cells also send signals via gap junctions that regulate the initiation of meiotic maturation to the oocyte; this function is discussed in detail below.

Signaling between the oocyte and granulosa cells does not run only in one direction. Several growth factors produced by the oocyte that act on the granulosa cells have been identified (Fig. 3) (Mottershead et al., 2015; Peng et al., 2013; Chang et al., 2016). The best-known are two members of the transforming growth factor β family, GDF (growth-differentiation factor) 9 and BMP (bone morphogenetic protein) 15. Both factors are produced by growing oocytes, although the relative portions and timing of synthesis may vary among species. Both can act as diffusible factors in vitro, although this does not exclude the possibility that, in vivo, they may be tethered to the oocyte surface. In the absence of either or both growth factors, granulosa cells show defects in proliferation and differentiation and they fail to undergo a process termed cumulus layer expansion at the time of oocyte maturation and ovulation. FGF (fibroblastic growth factor) 8 produced by oocytes also influences granulosa cell differentiation and activity. Importantly, in the mouse, production of GDF9 by the oocyte is essential, via its effect on granulosa cell physiology, for normal oocyte development. Thus, the oocyte actively modifies its microenvironment to ensure normal differentiation.

Fig. 3 Communication between the growing oocyte and neighboring granulosa cells. Gap junctions link the granulosa cells to the oocyte and to each other and permit the passage of small molecules. Glucose and certain amino acids are poorly taken up by the oocyte, which relies on the granulosa cells to provide glucose-derived pyruvate and the amino acids. Pyruvate may be transferred to the oocyte through gap junctions or by diffusion. Cholesterol synthesized by the granulosa cells is also transferred to the oocyte. The oocyte secretes several growth factors, including GDF9, BMP15 and FGF8B, that help to regulate granulosa cell differentiation and function.

Apart from the enormous increase in volume, what happens during oocyte growth? Below, I describe several key events, though many equally important changes occur and others certainly remain to be identified. Early during its growth, the oocyte secretes a family of glycoproteins that become assembled into an extracellular matrix termed the zona pellucida (Wassarman and Litscher, 2013). The zona pellucida completely envelopes the growing oocyte, reaching a final thickness of about 15 μm in humans. It serves at least two functions: first, because fertilization triggers modifications to the zona pellucida that prevent sperm penetration through it, it acts as a barrier to polyspermic fertilization; second, it is thought to protect the embryo from becoming trapped within the oviduct, thereby enabling it to reach the uterus where it will implant.

Because the zona pellucida physically separates the oocyte from the adjacent granulosa cells that supply it with essential nutrients and signals via gap junctions, a mechanism is required to enable the two cells to remain in physical contact. This mechanism consists of finger-like extensions of the granulosa cells, termed transzonal projections (TZPs), that traverse the zona pellucida to reach the oocyte (Fig. 4) (Li and Albertini, 2013; Clarke, 2017). The gap junctions connecting the granulosa cells to the oocyte are located where the tips of the TZPs contact the oocyte plasma membrane.

Growing oocytes also produce a large quantity of messenger RNAs. Some mRNAs synthesized by the growing oocyte are translated immediately to provide the proteins that sustain growth, but many others remain silent (Fig. 5) (Kang and Han, 2011; Svoboda et al., 2015; Clarke, 2012; Reyes and Ross, 2016). These stored mRNAs will be translated during either meiotic maturation or after fertilization, which are periods when the oocyte is transcriptionally silent. Although the oocyte may employ multiple strategies to identify whether specific mRNA species should be translated or stored, a well-characterized mechanism relies on a specific U-rich sequence, termed the cytoplasmic polyadenylation element (CPE), that is located in the 3'-untranslated region (3'-utr) within about 200 nt of the polyadenylation signal. The poly(A) tail of mRNAs bearing an appropriately positioned CPE becomes shortened (deadenylated) in growing oocytes and the mRNAs are likely stored in ribonucleoprotein particles in cytoplasm. Thus, unlike the case in many other cell types, deadenylation of an mRNA in oocytes is not coupled to its degradation.

Growing oocytes also generate an enormous number of mitochondria (St John, 2014). Although a wide range of values have been reported and there may be significant differences among species, the number in a fully grown oocyte could be conservatively estimated to be at least 150,000. As in the case of the mRNAs, this huge accumulation reflects the fact that embryos do not generate new mitochondria until after the embryo has implanted into the uterus and begun to grow in size. Other changes that occur during oocyte growth include the synthesis of membrane-bound vesicles, termed cortical granules (Cheeseman et al., 2016), whose contents will modify the zona pellucida following fertilization to prevent polyspermy, the assembly of a cytoplasmic lattice that may act as a storage unit for ribonucleoprotein particles carrying silent mRNAs (Liu et al., 2017), and the methylation of specific cytosine residues in DNA that establishes the female genomic imprinting pattern (Kelsey and Feil, 2013).

As oocytes approach full-size, the chromatin undergoes a morphological change termed the non-surrounded nucleolus (NSN) to surrounded nucleolus (SN) transition and transcriptional activity drops to an essentially undetectable level and the. Although the NSN–SN transition and transcriptional arrest are closely coupled temporally, their mechanistic link remains to be fully elucidated. Nor is the function of the transcriptional arrest in fully grown oocytes well-understood. It is worth noting that oocytes stop growing once they reach a species-characteristic size and it is interesting to speculate whether transcriptional arrest is the cause or the consequence of the growth arrest.

Meiotic Maturation

Near the end of the growth phase, oocytes acquire the ability to undergo meiotic maturation—the final stage of oocyte development before fertilization. During maturation, the oocyte, which has been arrested at late G2 of the cell cycle since entering meiosis during fetal life, enters M-phase, completes the first meiotic division and becomes arrested at metaphase of the second meiotic division (metaphase II). These divisions are discussed in more detail below; first, I will describe how maturation is controlled.

Fig. 4 Specialized structures that enable the oocyte and granulosa cells to maintain contact. The elaboration of the zona pellucida by the growing oocyte physically separates it from the adjacent granulosa cells. Contact between the two cell types is maintained by narrow cytoplasmic fingers, termed transzonal projections (TZPs, arrows), that extend from the granulosa cells through the zona pellucida to the surface of the oocyte. The gap junctions that metabolically couple the two cell types and are essential for oocyte growth are located at the tips of the TZPs. Granulosa cell–oocyte contact via TZPs is maintained throughout oocyte growth but is lost during meiotic maturation.

Fig. 5 Regulation of mRNA translation during growth and maturation. Upper: Growing oocytes. Most newly transcribed mRNAs are polyadenylated at the 3'-end in the nucleus. Following export to the cytoplasm, those following the default pathway remain polyadenylated and are translated. However, mRNAs carrying specific sequences in the 3'-untranslated region (3'-utr; red portion of mRNA in box) become deadenylated and translationally silent. The best-characterized sequence is the cytoplasmic polyadenylation element (CPE), typically located within 200 nt (double-headed arrow) of the poly(A) signal (AAUAAA). These silent mRNAs are very stable and thought to be stored in ribonucleoprotein particles. Lower: Maturing oocytes. Activation of CDK1 leads to phosphorylation and subsequent degradation of the CPE-binding protein, CPEB. This triggers elongation of the poly(A) tail (dashed arrow) and translational activation. *Dazl* mRNA is translationally activated by this mechanism, producing DAZL protein. DAZL in turn can bind to sequences in the 3'-utr of other mRNAs, triggering their polyadenylation and translational activation. Such mechanisms enable protein synthesis to be temporally regulated during maturation.

Maturation is initiated physiologically by luteinizing hormone (LH) released by the pituitary gland. Through a series of signaling steps described below, this leads to activation of cyclin-dependent kinase (CDK) 1 within the meiotically immature oocyte (Conti et al., 2012; Jaffe and Egbert, 2017), which has been arrested at late G2 of the cell cycle since entering meiosis during embryonic development, driving it into M-phase. Although fully grown immature oocytes contain CDK1, it is maintained—until the LH release—in an inactive form as follows (Fig. 6). NPPC (natriuretic peptide C) secreted by the mural granulosa cells of the follicle binds to and activates the G-protein coupled membrane receptor, NPR2 (natriuretic peptide receptor 2), on the mural and cumulus granulosa cells, triggering production of the nucleotide, cyclic (c) GMP (Zhang et al., 2010). Via the gap junctions located at the tips of the TZPs, cGMP flows from the granulosa cells into the oocyte, where it inhibits the activity of phosphodiesterase (PDE) 3A. This inhibition allows the concentration of cAMP, which is constitutively synthesized by the oocyte, to remain elevated. cAMP activates protein kinase A, which indirectly maintains inhibitory phosphorylation of specific sites on CDK1.

The preovulatory release of LH and binding to its receptor (LHGCR) located on the mural granulosa cells of the follicle (LHGCR is also present on the thecal cells) causes them to release ligands that bind to the epidermal growth factor receptor (EGFR) located on both the mural and cumulus granulosa cells. Via mechanisms that remain to be fully elucidated, activation of LHGCR and EGFR

Fig. 6 Regulation of meiotic maturation. A. Before the activation of the LH receptor (LHCGR), the mural granulosa cells produce and release NPPC, which activates its receptor, NPR2, located on both mural and cumulus granulosa cells. Active NPR2 generates cGMP, which diffuses through gap junctions and reaches a concentration in the oocyte that is sufficient to inhibit phosphodiesterase (PDE) 3A. This allows the concentration of cAMP, produced in the oocyte by adenyl cyclase (AC) coupled to G-protein coupled receptor (GPR) 3, to remain high, thereby maintaining CDK1 in a hyperphosphorylated inactive form. B. Binding of LH to LHCGR triggers the release of ligands from the mural granulosa cells that activate EGFR on the mural and cumulus granulosa cells. cGMP levels within the granulosa cells fall due both to inhibition of its synthesis owing to dephosphorylation of NPR2 and (later) reduced production of NPPC and to increased hydrolysis owing to activation of PDE5A in the granulosa cells. The relative contribution of LHCGR-mediated and EGFR-mediated signaling to these events remains to be fully elucidated. As the concentration of cGMP within the granulosa cells falls, it flows out of the oocyte to equalize its concentration throughout the granulosa cell-oocyte compartment. The decreased cGMP in the oocyte permits PDE3A to become active and hydrolyze cAMP, enabling dephosphorylation and activation of CDK1.

turns off production of cGMP by the granulosa cells, leading to a drop in its concentration within the oocyte. This permits the activation of PDE3A and consequently a decrease in intra-oocyte cAMP and activation of CDK1. In mice, no new protein synthesis within the oocyte is required to activate CDK1 and initiate maturation; in other mammals, however, new protein synthesis—possibly of cyclin B1, the regulatory subunit of CDK1—may be required.

The earliest easily identified morphological indicator of maturation is the dissolution of the nuclear envelope, termed germinal vesicle breakdown (GVBD). The chromosomes condense and progressively become aligned in the center of the first meiotic spindle (Holt et al., 2013; Polanski, 2013; Howe and FitzHarris, 2013) (Fig. 7). The poles of oocyte spindles lack centrioles; instead, they are generated by the acentriolar microtubule-organizing centers (aMTOCs) and associated proteins that are opposed to the nucleus of immature oocytes. Alignment of the chromosomes on the spindle is achieved by balanced forces of microtubules, termed K-fibers, that run from the kinetochores of each chromosome to each pole of the spindle (other microtubules run between the poles of the spindle) and thereby pull the chromosomes in opposing directions. A mechanism termed the spindle assembly checkpoint (SAC) ensures that the first meiotic division is not initiated until the chromosomes have become correctly aligned.

Once chromosomal alignment has been achieved, thereby satisfying the SAC, a protein termed CDC20 is released from an inhibited state (Fig. 8). CDC20 activates the APC/C (anaphase-promoting complex/cyclosome), which in turn degrades two key protein targets—cyclin B1 and securin. Degradation of cyclin B1 inactivates CDK1, triggering exit from M-phase of the cell cycle. In parallel, degradation of securin enables activation of separase, a protease. The target of separase are proteins known as cohesins, which hold homologous chromosomes together. Degradation of cohesins located on the arms of the chromosomes enables the homologues to be pulled to opposing poles of the spindle, a process that is achieved by the shortening of the K-fibers. Importantly,

Fig. 7 Translocation of the meiotic spindle to the oocyte cortex to permit asymmetric cytokinesis. The immature oocyte of the mouse contains a cytoplasmic actin mesh as well as cortical actin (red) and a small number of microtubule-organizing centers (yellow) located near the nuclear membrane. These lack centrioles, so are termed acentriolar (aMTOC). At the time of GVBD, the actin meshwork disappears and a process of fragmentation generates several aMTOCs, which associate with the condensing chromosomes. The aMTOCs organize the poles of the spindle, where myosin II (brown) is also present. The spindle contains both long microtubules running between the poles and shorter microtubules (both shown in green), termed K-fibers, running between the poles and chromosomal kinetochores. Balanced tension between K-fibers running in opposite directions helps to align the chromosomes in the middle of the spindle, thus satisfying the spindle assembly checkpoint. Concomitantly, a cytoplasmic actin meshwork reforms, the cortical actin thickens and the spindle begins to drift off-center. Interactions between myosin II and the cortex amplify the initial displacement and thus pull (arrow) the spindle towards the thickened cortex where it becomes anchored in preparation for the first meiotic division and cytokinesis.

Fig. 8 Initiation of the first meiotic division. Upper: When the spindle-assembly checkpoint is satisfied, CDC20 is released from an inhibited state and is able to activate the anaphase-promoting complex/cyclosome (APC/C). The APC/C degrades cyclin B1, thereby inactivating CDK1 and allowing the oocyte to move from M-phase to anaphase. The APC/c also degrades securin, thereby freeing separase that is able to degrade cohesin. The loss of cohesin enables homologous chromosomes to separate and thus move to opposite poles of the spindle at anaphase. Lower: Maternal (red) and paternal (blue) homologous chromosomes are held together at metaphase I by cohesin (black rings). Degradation of cohesin is necessary for the homologues to separate. The shugoshin protein (brown) located near the centromeres (yellow) locally protects cohesin from degradation at this time, so that sister chromatids remains tightly associated. Degradation of centromeric cohesin is required for the second meiotic division that will occur after fertilization.

in contrast to the cohesins located on the chromosomal arms, the cohesins associated with the centromeric regions of the chromosomes is protected from degradation, via the shugoshin protein. This ensures that sister chromatids remain associated during the first meiotic division. Mis-segregation of chromosomes during the first meiotic division is the most frequent origin of fetal aneuploidy. Following completion of the first meiotic division, the chromosomes retained in the oocyte rapidly become aligned on the second meiotic spindle. The oocyte becomes arrested at this stage, however, and does not complete the second meiotic division until it is activated by fertilization or by parthenogenetic agents. Meiotic arrest at metaphase II is achieved by stabilization of CDK1.

A remarkable feature of meiotic maturation is the extreme asymmetry of the cytokineses associated with the first and second meiotic divisions, which generate one very large cell—the oocyte—and one small cell—the first and second polar bodies, respectively. Thus, in contrast to the meiotic divisions in males, which generate four germ cells, these divisions in females generate only one germ cell. It is necessary to retain a large oocyte because the mitotic cleavage divisions following fertilization will divide it into many small cells, termed blastomeres, before the embryo implants into the uterus and begins to grow. To achieve the asymmetric cytokinesis, the meiotic spindle must be translocated to the cortex (periphery) of the oocyte. This depends on an actin meshwork in the cytoplasm, including an actin cage that encloses the spindle (Chaigne et al., 2017) (Fig. 7). This meshwork enables the caged spindle to be carried to the cortex through a process that depends on myosin II located at the poles of the spindle. It is thought that, owing to a slight off-centering of the nucleus in the immature oocyte, the spindle is initially displaced slightly towards one region of the cortex; subsequently, this displacement is amplified by a positive-reinforcement mechanism as the leading edge of the spindle approaches the cortex. Concomitantly, the actin-rich cortex thickens owing to increased assembly of actin fibers and, due to the exclusion of myosin II, becomes softer. This change in cortical tension, which must be gated within a narrow range and is regulated by CDK1 via activation of MAP (microtubule-associated protein) kinase, is essential for proper migration and positioning of the spindle.

These so-called nuclear events of maturation are accompanied by a diverse array of cytoplasmic changes. These include actin-mediated transport of membrane-bound vesicles termed cortical granules, which play a key role in preventing polyspermic fertilization, from the cytoplasm to the cortex and aggregation of mitochondria around the meiotic spindle. Notably, a subset of previously silent mRNAs become translationally activated (Fig. 5). The most extensively characterized mechanism involves the CPE. Its associated protein, CPEB, becomes phosphorylated early during maturation and is subsequently largely degraded (Clarke, 2012; Kang and Han, 2011; Reyes and Ross, 2016; Chen et al., 2013). Concomitantly, the poly(A) tail of CPE-containing mRNAs lengthens and these mRNAs become translationally activated. Whether phosphorylation or degradation of CPEB enables lengthening, as well as whether it is due to increased activity of poly(A) polymerases or decreased activity of deadenylases remain to be fully established. However, the translational activation of specific CPE-containing mRNAs, such as *Ccnb1* (cyclin B1), are essential for the completion of maturation. In addition to the CPE, other sequences in the 3'-utr also control mRNA translational activity during maturation (Chen et al., 2013). The *Dazl* mRNA contains CPEs and is translationally activated early during maturation. The newly synthesized DAZL protein then binds to specific sequences in the 3'-utr of mRNAs that may not contain a CPE, activating their translation. Such mechanisms enable the translation of different mRNA species may be temporally regulated during maturation.

Once the oocyte has completed meiotic maturation, having reached metaphase II, it becomes developmentally arrested. Now termed an egg, its developmental journey is complete. The egg awaits fertilization, which will release it from developmental arrest, enabling the second meiotic division to be completed and embryogenesis to begin.

Oocyte Meiotic Arrest

Introduction

The female germ cells, oocytes, arise from the primordial germ cells during development of the fetus. Following a round of DNA replication the cells enter meiosis progress to the dictyate stage of first meiotic prophase (prophase I) at about the time of birth, at which point meiosis arrests and the oocytes display a characteristic large nucleus called the germinal vesicle (GV). The diplotene arrest in oocyte may last for several months or years in follicular microenvironment depending on the mammalian species. These prophase I arrested oocytes are referred to as primordial oocytes and reside in primordial follicles. During follicular growth, the somatic cells divide to form several layers, the oocyte enlarges, and a fluid-filled antrum begins to form. Some follicles at the early antral stage are "recruited" by follicle-stimulating hormone (FSH) from the pituitary to continue growing and develop into preovulatory antral follicles (Graafian follicles, Fig. 1). Antrum formation physically separates the granulosa cells into a mural granulosa cell compartment along the follicle wall and a cumulus cell compartment surrounding the oocyte. The meiotic arrest of oocytes within preantral follicles is caused by inherent factors in the oocyte and correlates with low levels of activity by cell cycle regulatory proteins. Once the growing oocyte reaches its full size and an antral space begins to form, the oocyte acquires the ability to complete meiosis. However, these meiotically competent oocytes maintain meiotic prophase arrest until the preovulatory surge of luteinizing hormone (LH) from the pituitary gland triggers the resumption of meiosis during the estrous or menstrual cycle (Fig. 1). The process by which the oocyte completes the first meiotic division and progresses to metaphase of the second meiotic division is called oocyte maturation. Germinal vesicle breakdown (GVB) is the first change occurring, and is widely used as an experimental criterion for assessing meiotic resumption or oocyte maturation.

In 1935, Pincus and Enzmann demonstrated that rabbit oocytes could resume meiosis spontaneously without hormonal stimulation when they were liberated from antral follicles and cultured under simple nutritionally supportive conditions. Such spontaneous maturation of oocytes cultured either denuded of their cumulus cells or within their cumulus complex is confirmed in all mammalian species examined, including human. Interestingly, the time course of spontaneous maturation is similar to that of hormonal stimulation in vivo. These observations lead to general acceptance of the hypothesis that the somatic cells of the antral follicle provide a signal to the oocyte that keeps it arrested at prophase I. This hypothesis is further corroborated by the studies that co-culture of oocytes with follicular granulosa cells, granulosa cell extract, and follicular fluid inhibits oocyte maturation. The inhibitory action of granulosa cells is effective from small to medium sized follicles, but is significantly lower in follicles yielding mature oocyte. For a long time, many studies focus on identifying the factors participating in the maintenance of meiotic arrest, and lead to partial characterization and purification of a factor, oocyte maturation inhibitor (OMI), from follicular fluids. This inhibitory effect is not species specific; thus human follicular fluids inhibit the maturation of porcine and rat oocytes, bovine follicular fluids inhibit hamster oocytes, and porcine follicular fluids inhibit the maturation of rat oocytes. In 1976, Tsafiri et al. revealed that OMI had a low molecular weight (about 2000 Da), and the activity was lost when it was treated with protease. These results suggest that OMI is a peptide of low molecular weight. The inhibitory effect of OMI requires the mediation of cumulus cells surrounding the oocyte, since OMI inhibits the resumption of meiosis by oocytes cultured within their intact cumulus cells, but has no inhibitory effect on the maturation of denuded oocytes (Tsafiri and Pomerantz, 1986). LH overcomes the inhibitory effect of OMI, supporting that OMI has a physiological role in the regulation of meiosis. Some investigators are unable to demonstrate OMI activity of follicular preparations. These varying findings may be related, at least in part, to the low OMI activity of some batches of follicular fluid

Fig. 1 Ovarian follicle development in mammal. The follicle consists of somatic cells surrounding an oocyte (yellow). Oocytes within the primary and preantral follicles are meiotically incompetent. At the early antral stage, the oocytes acquire meiotic competence, but are held in meiotic arrest by the signaling from somatic cells. These early antral follicles are recruited for further growth by follicle-stimulating hormone (FSH), and become preovulatory follicles. The preovulatory follicle develops luteinizing hormone (LH) receptors on the mural granulosa cells. A surge of LH stimulates the oocyte to resume meiosis (maturation) and ovulation.

and of granulosa cell cultures. Collectively, these results support the notion that the inhibitory influence of the follicle is due to a factor, OMI, produced by granulosa cells. Purification of OMI to homogeneity will allow the assessment of the exact role of OMI in meiotic arrest in mammals.

Cyclic AMP

Cyclic adenosine 3',5'-monophosphate (cAMP) is a key second messenger regulating oocyte maturation. [Cho et al. \(1974\)](#) were the first to propose that spontaneous maturation of mouse oocytes in vitro when released from their follicles can be reversibly blocked by addition of a derivative of cAMP. Further studies indicate that oocyte maturation can be blocked by adenylyl cyclase activators, membrane permeant cAMP analogs or cAMP phosphodiesterase inhibitors, such as hypoxanthine or 3-isobutyl-1-methylxanthine (IBMX). Moreover, oocytes resume meiosis spontaneously in parallel with decreases in cAMP levels. These findings, confirmed in numerous mammalian species, indicate that maintenance of meiotic arrest in meiotically competent oocytes depended on high levels of cAMP within the oocyte.

Intraoocyte cAMP regulates the maturation-promoting factor (MPF) activity through stimulation of cAMP-dependent protein kinase A (PKA). MPF is the protein complex of cyclin-dependent kinase 1 (CDK1) and cyclin B (CyB), and its activity is regulated by the phosphatase cell division cycle 25B (CDC25B) and the kinases Wee1B and myelin transcription factor 1 (MYT1); CDC25B dephosphorylates CDK1, whereas WEE1B, and MYT1 phosphorylate CDK1. High cAMP levels result in the phosphorylation of CDK1 and inactivation of the MPF complex so that the oocyte is arrested at the dictyate stage of prophase I ([Fig. 2](#)).

Cyclic AMP Synthesis

Cyclic AMP could be produced either by the oocyte or by the follicular somatic cells that surround it. A long-standing hypothesis is that cAMP is generated by somatic cells and continuously diffuses into oocytes through heterologous gap junctions between cumulus cells and oocytes. Although the inhibitors of gap junction permeability induce oocyte maturation ([Sela-Abramovich et al., 2006](#)), the permeability of these junctions to cAMP has not been definitively determined. The increasing evidences indicate that the oocyte itself produces sufficient cAMP to maintain meiotic arrest.

It is reported that meiotic arrest could be interrupted by microinjection of either an antibody of stimulatory G protein (Gs) or a dominant negative form of a subunit of Gs into follicle-enclosed oocytes, suggesting that the Gs-adenylyl cyclase mediates production of cAMP within the oocyte. The G-protein-coupled, Gs-linked receptor, GPR3, is expressed in mouse oocyte, and adenylyl cyclase (ADCY) is found at the oolemma. GPR3 or ADCY3-deficient oocytes show precocious resumption of meiosis within the antral follicles ([Mehlmann et al., 2004](#)). GPR3 is also as the predominant receptor signaling for meiotic arrest in human oocytes.

Fig. 2 Oocyte signaling maintaining meiotic arrest at diplotene stage of prophase I in the antral follicle. GPR3/12, activated constitutively by an unknown ligand endogenous to the oocyte, activates Gs, which stimulates ADCY to cause an elevation of cAMP. The activity of the cAMP phosphodiesterase, PDE3A, is kept low by cGMP of somatic cell origin, thus preventing the breakdown of cAMP and maintaining high levels of cAMP within the oocyte. The increased level of cAMP increases PKA activity. The increased PKA activity inactivates CDC25B phosphatase and activates Wee1B/MYT1 kinase that results in phosphorylation of CDK1 and inactivation of MPF (CDK1/CyB complex), and therefore maintains meiotic arrest. *GPR3/12*, G-protein-coupled receptor 3 and 12; *Gs*, guanine nucleotide binding protein, α stimulating; *ADCY*, adenylyl cyclase; *cAMP*, cyclic adenosine 3',5'-monophosphate; *cGMP*, cyclic guanosine 3',5'-monophosphate; *PDE3A*, phosphodiesterase 3A; *PKA*, protein kinase A; *MPF*, maturation promoting factor; *CDK1*, cyclin-dependent kinase 1; *CyB*, cyclin B; *CDC25B*, cell division cycle 25B; *MYT1*, myelin transcription factor 1.

A closely related receptor, GPR12, has been shown to be expressed specifically in rat oocytes, and serves an analogous function in rat oocytes. These receptors exhibit constitutive activity that is independent of granulosa cell influence, but the natural ligand(s) has not been identified. Taken together, the above findings strongly suggest that meiotic arrest is dependent on continuous cAMP signaling through active GPR/Gs/ADCY endogenous to the oocyte (Fig. 2). Although the transfer of cAMP from surrounding cumulus cells to oocytes is possible, it is not sufficient by itself to maintain meiotic arrest.

Cyclic AMP Degradation

Intracellular concentration of cAMP depends on the synthesis by ADCY and the hydrolysis by cyclic nucleotide phosphodiesterases (PDEs). It has been shown that maintenance of meiotic arrest is associated with undetectable cAMP-PDE activity. In 1998, Wiersma et al. reported that injection of PDE3 inhibitors into rats and mice prevented meiotic resumption without affecting ovulation, strongly suggesting an essential role of the PDE3 family in regulating oocyte maturation via cAMP degradation. PDE3A is the major PDE expressed in mouse, rat, monkey, and human oocytes. The selective PDE3A inhibitors such as cilostamide and milrinone maintain oocyte meiotic arrest in several mammalian species, and PDE3A activity increases during gonadotropin-stimulated oocyte maturation. Vaccari et al. (2008) reported that oocytes deficient in PDE3A had the continuous cAMP accumulation and meiotic arrest even after removal from the follicle, indicating that the meiotic arrest is maintained by constitutive cAMP signaling associated with a lack of PDE3A activity. Depleting both of GPR3 and PDE3A genes allows spontaneous meiosis resumption in vivo as depletion of GPR3 alone, suggesting that PDE3A is downstream of GPR3. These results illuminate that intraoocyte cAMP levels are regulated via control of PDE3A-mediated degradation, rather than endogenous synthesis. Inhibition of PDE3A activity is essential for sustaining elevated cAMP levels that maintain meiotic arrest.

Cyclic GMP

In 1980, Hubbard reported that cyclic guanosine 3',5'-monophosphate (cGMP) levels were highest at dioestrus but lowest during oestrus in hamster ovary, suggesting a functional relationship between cGMP levels and meiosis. Many studies show that cGMP plays an important role in the maintenance of meiotic arrest. Cyclic GMP levels decrease during oocyte spontaneous maturation. Exposure of oocytes to the cGMP analog 8-Br-cGMP, or to the cGMP PDE-specific inhibitors maintains meiotic arrest in several mammalian species.

It is known that cGMP shows an inhibitory effect on PDE3A activity via competition with cAMP in the hydrolysis process. PDE3A hydrolyzes both cAMP and cGMP, but the velocity of cAMP hydrolysis is one order of magnitude higher than that for cGMP hydrolysis. Consistent with these results, the microinjection of a cGMP-specific PDE5 into oocytes causes meiotic maturation of wild-type oocytes, but this effect is absent in PDE3A-deficient oocytes. Moreover, cGMP suppresses cAMP hydrolysis in oocyte extracts, suggesting that cGMP maintains meiotic arrest through the inhibition of PDE3A activity. Guanylyl cyclase agonists have inhibitory effects on spontaneous meiotic resumption in cumulus-oocyte complexes (COCs), but not in denuded oocytes, and the inhibition of cGMP production by the somatic cells leads to a decrease in oocyte cGMP and meiotic resumption (Norris et al., 2009), suggesting that the oocyte depends on the somatic cells for its supply of cGMP. Cyclic GMP diffuses into oocytes via heterologous gap junctions to inhibit PDE3A activity (Fig. 2). This inhibition sustains a high concentration of intraoocyte cAMP sufficient to maintain meiotic arrest. Thus, cGMP of somatic cell origin is a critical component required to maintain meiotic arrest.

NPPC

Cyclic GMP can be produced by nitric oxide (NO) and natriuretic peptides. NO, a chemical messenger enzymatically produced by three isoforms of nitric oxide synthases (NOS), activates soluble guanylyl cyclase. NO donor sodium nitroprusside has the inhibitory effect on mouse oocyte spontaneous maturation only in a high concentration, with an increase in the percentage of atypical. However, knockouts of *Nos1* and *Nos2* affect ovulation, and knockout of *Nos3* appears to impair oocyte development. The role of NO appears to be not in the regulation of meiotic arrest.

The natriuretic peptides, including type A (NPPA, also known as ANP), type B (NPPB, also known as BNP), and type C (NPPC, also known as CNP), activate particulate guanylyl cyclase family. In general, NPPA and NPPB activate natriuretic peptide receptor 1 (NPR1, also known as GC-A, NPRA), and NPPC activates receptor NPR2 (also known as GC-B, NPRB). NPPA and NPPB are cardiac hormones, and have an important role in the regulation of cardiovascular homeostasis. It is reported that NPPA slightly inhibits spontaneous meiotic resumption of rat oocytes. However, NPPA and NPPB genes in mouse ovary could not be detected by in situ hybridization, and by specific riboprobes. Moreover, the activity of these ligands could not be detected in inhibiting meiotic resumption of mouse oocytes or in promoting elevated cGMP levels in vitro. All these results indicate that NPPA and NPPB do not seem to be the crucial mechanism of meiotic arrest.

NPPC, on the contrary, is expressed in a wide variety of central and peripheral tissues and acts locally as autocrine and paracrine regulator. NPPC and its cognate receptor NPR2 are reported in rat follicles, and show variation during the estrous cycle. Zhang et al. (2010) found that NPPC of granulosa cell origin acted on the NPR2 receptor in cumulus cells to stimulate cGMP synthesis (Fig. 3). This provides a critical piece to understanding the molecular basis for maintenance of meiotic arrest. NPPC gene is expressed

Fig. 3 Somatic cell signaling regulating oocyte meiosis. NPPC produced by mural granulosa cells stimulates the generation of cGMP by cumulus cell NPR2. Cyclic GMP, diffusing into oocyte via gap junctions, maintains high cAMP levels and meiotic arrest by the inhibition of PDE3A activity. ODPF promotes cumulus cell expression of NPR2 to elevate cGMP levels for meiotic arrest. FSH, through estrogen and other signaling, enhances NPPC/NPR2 expression during antral follicular development. LH-induced EGF-like growth factors decrease NPPC content and NPR2 activity, resulting in cGMP decrease and meiotic resumption. *NPPC*, natriuretic peptide type C; *NPR2*, natriuretic peptide receptor 2; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *EGF-like factors*, epidermal growth factor-like factors. *cGMP*, cyclic guanosine 3',5'-monophosphate; *cAMP*, cyclic adenosine 3',5'-monophosphate; *GPR3/12*, G-protein-coupled receptor 3 and 12; *Gs*, guanine nucleotide binding protein, α stimulating; *ADCY*, adenylyl cyclase; *ODPF*, oocyte-derived paracrine factors; *PDE3A*, phosphodiesterase 3A.

predominantly in mouse mural granulosa cells (MGCs), which line the inside of the follicular wall, and in contrast, NPR2 gene is most concentrated in the cumulus cells surrounding the oocyte. NPPC prevents spontaneous resumption of cumulus cell-enclosed mouse oocytes in vitro, and increases cumulus cell and oocyte cGMP levels. NPPC do not prevent spontaneous resumption of denuded oocytes, possibly for the lack of NPR2 receptor in oocyte. Importantly, mutations in either the NPPC or NPR2 gene in mice result in failure to maintain meiotic arrest and precocious meiotic resumption in oocytes within antral follicles. Further study shows that both connexin-43 (GJA1) and connexin-37 (GJA4) gap junctions are involved in NPPC-mediated meiotic arrest. Thus, NPPC from follicular MGCs stimulates the generation of cGMP by NPR2 in cumulus cells. Cyclic GMP diffuses into oocyte via heterologous gap junctions and maintains meiotic arrest by inhibiting PDE3A activity and cAMP hydrolysis (Fig. 3). The expression of NPR2 on granulosa cells suggests that cGMP generated in granulosa cells via autocrine role may also contribute to meiotic arrest. In mammals, oocyte maturation must be coordinated precisely with ovulation to produce a developmentally competent egg at the right time for fertilization. Therefore, NPPC/NPR2 prevents precocious meiotic resumption in oocytes, which is critical for maturation and ovulation synchrony and for normal female fertility.

It has long been known that the granulosa cells of follicles produce OMI that keeps oocyte arrested at the dictyate stage of prophase I. Interestingly, granulosa-derived NPPC has the character similar to the OMI: a 22 amino acid residues peptide with molecular weight of 2197.6, action on cumulus cell NPR2, and the identical sequences among mouse, rat, pig, and human. NPPC from human inhibits oocyte maturation of mouse, rat, pig, and cattle. Moreover, LH can overcome the inhibitory effect of NPPC. A better understanding of NPPC on meiotic arrest will allow the assessment of the detailed mechanism(s) in the regulation of meiosis in mammals.

The Regulation of NPPC/NPR2

Oocyte-Derived Paracrine Factors

In general, oocyte-derived paracrine factors (ODPFs) affect cumulus cell differentiation, and granulosa cells have important endocrine functions. NPR2 gene is expressed predominantly in cumulus cells, and its expression could be promoted by ODPFs. The expression of NPR2 gene in cumulus cells decreases when the oocyte is removed, but could be restored when these cumulus cells culture with denuded oocytes. Further studies focus on growth differentiation factor 9 (GDF9), bone morphogenetic protein 15 (BMP15; also called GDF9B), and fibroblast growth factor 8B (FGF8B), the members of oocyte-secreted transforming growth factor- β (TGF- β) superfamily. Each of these three ODPFs slightly promotes expression of NPR2 gene by cumulus cells, and combinations of three proteins have the same effect as that of oocytes on promoting NPR2 gene expression in isolated cumulus cells

(Fig. 3). Knockout of Smad4, the central component of the canonical TGF- β signaling pathway, reduces NPR2 expression in cumulus cells, and the maintaining oocyte meiotic arrest is weakened, indicating that these ODPFs act on cumulus cells by the activation of SMAD (Sma and Mad-related protein) signaling pathway.

It is reported that the function of the NPPC/NPR2 system depends upon IMPDH activity for the production of cGMP and maintaining meiotic arrest. IMPDH is the rate-limiting enzyme required for the production of guanylyl metabolites and cGMP. Inhibition of IMPDH with mizoribine prevents NPPC/NPR2 from providing the sufficient levels of cGMP required for maintaining oocyte meiotic arrest. Interestingly, ODPFs, particularly GDF9-BMP15 heterodimer, also promote expression of IMPDH. Therefore, ODPFs could promote expression of IMPDH and NPR2 and elevate cGMP levels in cumulus cells for meiotic arrest. It has been long known that the follicular somatic cells are essential in maintaining oocyte meiotic arrest. However, the function of the somatic cells is surprisingly regulated by oocyte-derived paracrine signals. Thus, the maintenance of oocyte meiotic arrest is not unidirectional from the somatic compartment to oocytes but bidirectional, requiring orchestration by oocytes.

FSH

During each estrous cycle, FSH recruits some early antral follicles to continue growing and develop into Graafian follicles. It is reported that the expression of NPPC and NPR2 in rat ovary vary during the estrous cycle with maximal expression at proestrus. The treatment of equine chorionic gonadotropin (eCG), a glycoprotein hormone that possesses primarily FSH activity, stimulates NPPC gene expression in rodent MGCs and increases NPPC content in the ovaries. eCG also increases NPR2 gene expression in both MGCs and cumulus cells. However, FSH cannot stimulate the expression of NPPC and NPR2 genes in MGCs cultured in vitro, suggesting that FSH activity of eCG induces the expression of NPPC and NPR2 indirectly (Fig. 3). The distinct physiological action of FSH is to stimulate follicular growth. Thus, FSH-promoted NPPC and NPR2 insure their ability to maintain oocyte meiotic arrest during antral follicular development. Inappropriate expression of NPPC and NPR2 in the growing follicles may disrupt meiotic arrest and normal follicular development.

FSH increases estrogen levels by the aromatization of testosterone, which partially mediates FSH action. The injection of synthetic estrogen diethylstilbesterol (DES) promotes NPPC and NPR2 genes expression in rat ovary. In vitro, 17 β -estradiol (E2) increases the levels of NPPC and NPR2 genes in cultured mouse MGCs. E2 also stimulates the expression of NPR2 gene by cumulus cells, thereby augmenting NPPC ability to produce cGMP and maintain meiotic arrest of COCs. All these results implicate that the physiological role of estrogens may be involved in maintaining oocyte meiotic arrest via promoting the expression of NPPC and NPR2. However, the deletion of estrogen receptors shows slightly precocious meiotic resumption of oocytes within antral follicles. Thus, other pathways may participate in the regulation of NPPC and NPR2 expression maintaining meiotic arrest.

LH

Fully grown mammalian oocytes within Graafian follicles are held in meiotic arrest by NPPC/NPR2-produced cGMP until LH triggers oocyte maturation and ovulation during the estrous or menstrual cycle. It has been known that LH receptor activation, via a series of incompletely understood steps, ultimately causes a decrease in cAMP within the oocyte. Recent studies provide strong evidence that LH acts by decreasing cGMP synthesis in somatic cells, resulting in the decrease of intraoocyte cGMP levels. The reduction of cGMP levels in oocytes relieves the inhibition of PDE3A, resulting in the decrease of cAMP levels. Further studies show that LH decreases cGMP levels in follicular somatic cells by the reductions of NPPC/NPR2 expression and function (Fig. 3). The activation of LH receptor decreases NPPC gene and/or protein levels in mouse, rat, pig, and human ovaries (Kawamura et al., 2011). LH receptor signaling also decreases NPR2 gene levels in mouse cumulus cells. However, this decrease occurs after meiotic resumption. On the other hand, LH could induce meiotic resumption of oocytes within cultured follicles even in the present NPPC, suggesting that LH may decrease NPR2 guanylyl cyclase activity. Consistent with this, LH treatment rapidly causes NPR2 dephosphorylation in rat granulosa cells without the change of NPR2 protein levels (Egbert et al., 2014). This dephosphorylation results in the inactivation of NPR2 and the rapid reduction in follicle cGMP levels. Thus, LH decreases NPPC content and NPR2 activity, each of which is enough to induce oocyte maturation by decreasing cGMP levels in the somatic cells and then in oocytes. The timing of meiotic resumption and ovulation is so critical that multiple pathways may have evolved into the fail-safe mechanism to ensure normal female fertility.

It is well known that LH promotes the production of epidermal growth factor (EGF)-like growth factors in MGCs, including amphiregulin (AREG), epiregulin (EREG), and betacellulin (BTC) in MGCs, which is essential for the regulation of oocyte maturation and ovulation (Park et al., 2004). The activation of EGFR by amphiregulin and EGF decreases NPPC gene levels in cultured granulosa cells. However, the EGFR inhibitor AG1478 partially reverses LH-induced the decrease of NPPC gene, suggesting that EGFR activity is not required for all of the LH-induced NPPC decrease. In COCs culture system that NPPC is used to prevent oocyte spontaneous maturation, EGF could decrease NPR2 activity of cumulus cells via the elevation of intracellular calcium concentrations. Further study shows that EGF-elevated calcium in cumulus cells decreases NPR2 affinity for NPPC and cGMP levels (Fig. 3), resulting in meiotic resumption (Hao et al., 2016). It needs to elucidate whether calcium also reduces NPR2 phosphorylation levels of cumulus cells as reported in a 293T cell line stably expressing NPR2.

It has been long hypothesized that the action of LH either relieves a maturation arresting substance from the somatic cells, or alternatively provides a positive maturation-promoting substance to override the follicular inhibition. Above data is consistent with a model in which LH removes the inhibitory function of NPPC/NPR2 to subsequently trigger oocyte maturation.

Glossary

Cystoblast Cyst forming cell in the *Drosophila ovariole*.

Cyst fragments Groups of interconnected cells released from a germline cyst by breakage of one or more of its intercellular bridges; unless single, the cells in each cyst fragment will still have the properties of a cyst.

Fusome Cytoplasmic organelle found in insect intercellular bridges thought to be important for synchronizing divisions and specifying the oocyte during cyst formation in *Drosophila*, has not been detected in mammalian cysts.

Germ cell nest Germ cells that clump together morphologically; the interconnected nature of such cells cannot be determined from morphological observation.

Germarium Structure at the anterior end of the ovariole in *Drosophila* where the germline stem cells reside.

Germline cyst A cluster of interconnected germ cells generated by mitotic divisions with incomplete cytokinesis.

Intercellular bridges The arrested cytokinesis furrows that join the cytoplasm of individual germ cells within a cyst.

Ovariole Subdivision of the *Drosophila* ovary where oocytes are produced.

Primordial follicle One primary oocyte surrounded several flattened pregranulosa cells, found in mammals.

Primordial germ cells (PGCs) Precursors of oocytes and sperm found in fetal gonads.

Ring canal *Drosophila* intercellular bridge.

Introduction

Germ cells throughout the animal kingdom develop in structures called germline cysts. These structures share several conserved characteristics and are most well studied in the *Drosophila* ovary. The cells that make up a germline cyst divide synchronously by mitosis from precursor cells, remain connected by intercellular bridges and share cytoplasm. This article will focus on our current understanding of these structures in mammalian fetal ovaries and in particular, the mouse.

Germline Cysts—The *Drosophila* Model System

Drosophila female germline cysts are the most the well-studied and will be described here as a frame work for the discussion of mammalian germ cell cysts. Each *Drosophila* ovary consists of about 16 ovarioles where eggs are produced (for reviews of *Drosophila* oogenesis see [Bastock and St Johnston, 2008](#); [De Cuevas et al., 1997](#); [Hudson and Cooley, 2014](#); [Spradling, 1993](#)). Each ovariole has eggs at various stages of development often referred to as an assembly line of egg production. Germline stem cells are found in the germarium, a structure at the anterior end of the ovariole. There are about two to three stem cells in each germarium and they divide to form a daughter germline stem cell and a cyst forming cell called the cystoblast. The cystoblast then divides exactly four times but cytokinesis is not completed leaving a structure of 16 connected germ cells called a germline cyst. The connections or intercellular bridges are also referred to as ring canals based on their appearance. In each *Drosophila* cyst, a cellular structure named the fusome plays an essential role in orientating centrosomes and thus to generate a branched cyst structure. In each *Drosophila* 16-cell cyst, two germ cells are connected by four intercellular bridges, two cells are connected by three bridges, four cells are connected by two bridges and eight cells are connected by one bridge. The fusome is a cytoplasmic organelle found within the intercellular bridges of the cysts in many insects ([Hirschler, 1955](#)). Under the electron microscope (EM), the fusome is recognized by a distinctive region that is rich in fibrils and endoplasmic reticulum (ER)-like vesicles but excluding mitochondria ([De Cuevas et al., 1997](#)). During oocyte formation in each *Drosophila* cyst, one of the two germ cells with four bridges collects cytoplasm from the remaining 15 cells and differentiates into an oocyte. The remaining 15 germ cells, namely nurse cells die in an apoptotic-like process after donating their cytoplasmic content. Transfer of nurse cell cytoplasm across the ring canals to the oocyte occurs slowly at first and then more quickly in a process called nurse cell dumping.

Conservation of Cysts and Features of Mammalian Cysts

Germline cysts have been found during gametogenesis in many vertebrates and invertebrates. Since the late 19th century, intercellular bridges connecting adjacent germ cells have been observed in a wide range of animals by using EM ([Fawcett et al., 1959](#)).

During the oogenesis of invertebrates and some lower vertebrates, oocyte production in the adult ovary is sustained by germline stem cells or oogonia. Germline cysts can be observed in the adult ovary of these animals, including worms (Gibert et al., 1984; Hirsh et al., 1976; Siekierska, 2003), insects (Gutzeit et al., 1993; Klag and Bilinski, 1993), fishes (Leu and Draper, 2010; Marlow and Mullins, 2008; Nakamura et al., 2010), amphibians (Coggin, 1973; Filosa and Taddei, 1976; Kloc et al., 2004; Ruby et al., 1970), lizards (Filosa and Taddei, 1976), and chicks (Skalko et al., 1972; Ukeshima and Fujimoto, 1991). During mammalian oogenesis, oocyte production is sustained by a pool of primary oocytes that form during fetal ovarian development. Germline cysts can be observed in mammalian fetal ovaries. Animals that have been examined include bats (Lechowska et al., 2012), mice (Ruby et al., 1969), rats (Franchi and Mandl, 1962), golden hamsters (Weakley, 1967), rabbits (Zamboni and Gondos, 1968), pigs (Bielanska-Osuchowska, 2006), bovines (Garverick et al., 2010; Russe, 1983), and humans (Gondos, 1973; Ruby et al., 1970). Germline cysts have been identified in adult testes during spermatogenesis in many invertebrates and vertebrates as well. The animals that have been examined include hydras, *Drosophila*, opossums, pigeons, rats, hamsters, guinea pigs, rabbits, monkeys, and humans (Fawcett et al., 1959).

The cell biology of mammalian germline cysts remains largely unknown but is beginning to be investigated in mice (see Fig. 1). In the mouse embryo, germ cell progenitors, primordial germ cells (PGCs) can be first identified at around embryonic day 5 (E5) (Wear et al., 2016). PGCs initially proliferate with complete cytokinesis while migrating into the gonad. Starting at E10.5, individual PGC proliferate with incomplete cytokinesis to form germline cysts in both fetal ovaries and testes (Lei and Spradling, 2013; Pepling and Spradling, 1998). Unlike the *Drosophila* cyst, in which 16 germ cells remain interconnected in a fixed geometry, mouse cysts become fragmented during and after cyst formation. On average, each PGC produce a 30-cell clone, which comprises about 5 cysts whose size ranging from 2 to about 30 cells. Cysts from a PGC cluster together with cysts derived from other PGCs form nests of germ cells in fetal ovaries (Fig. 2). At around E14.5, when mitosis ceases, germ cells in the cyst enter meiosis synchronously in the mouse fetal ovary (Lei and Spradling, 2013). Mouse cysts continue fragmenting into single cells (but still nesting together) from E14.5 to postnatal day 0 (P0). In the P4 ovary, germ cells become individualized due to nest breakdown (detailed in section five). These individual primary oocytes are enclosed by several pregranulosa cells to form primordial follicles. From E14.5 to P4, approximately 80% of the fetal germ cells undergo apoptosis during a process similar to the “nursing process” observed in *Drosophila* oogenesis (Lei and Spradling, 2016).

During oocyte differentiation in the human fetal ovary, PGCs are observed in the embryo of about 3 weeks, at the number of about 40 (Witschi, 1948). These germ cells continue to proliferate in the fetal ovary and the number of germ cell per ovary peaks at ~3.5 million by 5 months, indicating the end of germline cyst formation in the human fetal ovary (Baker, 1963). Unlike in the mouse fetal ovary, where most germ cells develop at the same stage, such as cyst formation (E10.5–14.5), cyst fragmentation (E14.5–P0), nest breakdown (P0–P4), germ cells of each above stage can be observed in a relatively wide range of time during oocyte differentiation in the human fetal ovary. Germline cysts/intercellular bridges appear to be present between 50 days and 140 days/22 weeks (Hartshorne et al., 2009). Primordial follicles can be observed as early as 15 weeks, and the

Fig. 1 Germ cell development in the mouse ovary. Primordial germ cells arrive at the genital ridge at approximately E10.5 and germ line cysts form with cysts becoming fragmented during and after cyst formation. Mouse cysts continue to fragment into single cells but remain together in the nests. Starting at E13.5, germ cells enter meiosis and progress through prophase I. Subsequently, oocytes arrest in the diplotene stage beginning at E17.5. After birth, germ cell nests break apart and pregranulosa cells enclose individual oocytes to form primordial follicles.

Fig. 2 Germ cell morphology in the E14.5 mouse fetal ovary. VASA-expressing germ cells are clustered together in nests. Two germline cysts (red) are revealed by lineage marker yellow fluorescent protein (YFP) by the single-PGC lineage tracing approach (Lei and Spradling, 2013).

number steadily increases during the second trimester and plateaus in the third trimester with $\sim 350,000$ – $400,000$ /ovary at birth (Kerr et al., 2013). These primordial follicles formed in the fetal ovary, namely the ovarian reserve, serve as the only source for sustaining egg production in the adult ovary.

Cyst Formation, Structure, and Composition

As early as 1880–90s, intercellular bridges were described by several scientists when they studied cell division in limax eggs, arthropod cells, and trout embryos (Fawcett et al., 1959; Carnoy, 1885; Flemming, 1891; Hennequy, 1896; Mark, 1881). The intercellular bridges were initially considered as a transient structure during cytokinesis of mitotic division. In 1955, Burgos and Fawcett recognized intercellular bridges as “a normal occurrence” when studying spermatogenesis in the cat (Burgos and Fawcett, 1955). These early ultrastructural morphological studies lay the foundation for recognizing the mechanism of germline cyst formation through incomplete cytokinesis. By using EM, intercellular bridges were described as “short cylindrical channels bounded by an electron opaque membrane continuous with the plasma membrane of the conjoined cells” (Gondos, 1973). The morphology of intercellular bridges is highly conserved in vertebrates and invertebrates. A typical intercellular bridge is 0.5 – $3\ \mu\text{m}$ in diameter in mammals, and 0.5 – $10\ \mu\text{m}$ in *Drosophila* (Cooley, 1998; Greenbaum et al., 2011). While the importance of the fusome in *Drosophila* cyst formation has been demonstrated, the mechanism of cyst formation in other animals remain largely uncovered. Fusome-like structures have been found in the *Xenopus* ovary and dogfish testis (Kloc et al., 2004; Loppion et al., 2008), but have not been observed within the intercellular bridges in mammalian ovaries or testes (Greenbaum et al., 2011; Pepling and Spradling, 1998).

The structure of mouse cysts during oocyte differentiation has been investigated (Lei and Spradling, 2013; Pepling and Spradling, 1998). Similar to *Drosophila* cysts, mouse cysts are in branched structures. By the time cyst formation is completed in the E14.5 mouse ovary, about 14% of germ cells in cysts are connected by three or four intercellular bridges (Fig. 3). The mechanism underlying branched cyst formation in mice remains unknown. The fact that the fusome structure was not found in mouse cysts suggests that mammals may use a different mechanism to position centrosomes and spindles during cyst formation.

The molecular composition of intercellular bridges has been characterized in *Drosophila* female and male cysts and mouse cysts in adult testes. In *Drosophila* cysts, intercellular bridges are initially composed of proteins involved in contractile ring formation during cytokinesis, including anillin, septins, mitotic kinesin-like protein (MKLP), actin, and myosin II. As the bridges mature, myosin II and actin are lost in the bridges in male cysts. In contrast, actin remains a major component of the mature bridges in female cysts, anillin and septins are no longer present. Two female cyst-specific proteins, hu-li tai shao (Hts) and kelch, are essential for female bridge growth and expansion (Cooley, 1998).

The protein composition of the intercellular bridges in adult mouse testes was revealed by proteomic analyses (Greenbaum et al., 2007). Besides anillin, septin, MKLP, and Rac GTPase-activating protein (RacGAP) that are found in the cytokinesis machinery of somatic cells, germ cell-specific intercellular bridge proteins, including testis-expressed 14 (Tex14) and RNA-binding protein 44 (RBM44) were also identified. Tex14 is a highly conserved protein that is expressed in human testes (Houmard et al., 2009), the loss of Tex14 in mice led to defects in bridge formation and male infertility (Greenbaum et al., 2006).

Fig. 3 Left: A lineage-labeled 21-cell cyst (red, lineage marker YFP) in the E14.5 mouse fetal ovary. Intercellular bridges are revealed by immunostaining of a bridge marker Tex14 (green). Structure of the cyst is shown in the diagram on right. Adapted from Lei, L. and Spradling, A. C. (2016). Mouse oocytes differentiate through organelle enrichment from sister cyst germ cells. *Science* **352**, 95–99.

Regulation of Nest Breakdown and Follicle Formation

The regulation of cyst formation and oocyte specification in mammals is not well understood. Recently, however, headway has been made in our understanding of the genetic control of nest breakdown into individual germ cells and primordial follicle formation and can be broken down into several classes of regulatory molecules including steroid hormones, signaling pathways, transcription factors, and cell adhesion molecules (Table 1).

Several hormones have been implicated in the control of nest breakdown and follicle formation including at least two steroids and one polypeptide hormone. The steroid hormone estrogen is thought to be important for maintaining oocytes in nests and thus, must be downregulated for follicle formation to occur. Ovaries from adult female mice treated as neonates with estrogen or estrogenic compounds have more multiple oocyte follicles (MOFs) which are likely oocyte in nests that did not separate and subsequently became enclosed in follicles together (Iguchi et al., 1986; Jefferson et al., 2006; Suzuki et al., 2002). Exposure of neonatal mouse ovaries to estrogen in ovary organ culture reduced the number of single oocytes and increase the number of oocytes still in nests (Chen et al., 2007). In addition, the phytoestrogen genistein and synthetic estrogens diethylstilbestrol, ethinyl estradiol and bisphenol A (BPA) also blocked nest breakdown (Karavan and Pepling, 2012). Further, progesterone also inhibited nest breakdown and with estradiol had an additive effect. In contrast to steroid hormones, follicle stimulating hormone (FSH) was found to promote nest breakdown and primordial follicle formation in both hamsters and mice (Lei et al., 2010; Roy and Albee, 2000).

There is evidence for the involvement of several signaling pathways in the control of nest breakdown and primordial follicle formation. Several members of the transforming growth factor beta (TGFβ) superfamily are expressed in the developing ovary. Mutants for either *bone morphogenetic protein 15* (*Bmp15*) or *growth differentiation factor 9* (*Gdf9*) have more MOFs than normal mice suggesting defects in nest breakdown (Yan et al., 2001). Both gene products are oocyte-secreted TGFβ family members (Elvin et al., 2000). Treatment of ovaries with another TGFβ family member, activin A, promotes follicle formation (Bristol-Gould et al., 2006). In contrast, overexpression of activin antagonist, inhibin B causes an increase in MOFs (Mcmullen et al., 2001). One isoform of Follistatin, another activin antagonist, when deleted causes defects in nest breakdown (Wang et al., 2015; Kimura et al., 2011). *Lunatic fringe* (*Lfng*) mutants are infertile with MOFs (Hahn et al., 2005). LFNG belongs to the fringe protein family which function by regulating notch signaling (Bruckner et al., 2000; Hicks et al., 2000) suggesting that notch signaling may play a role in nest breakdown. Interestingly, In *Drosophila*, *fringe* mutants also have follicles with more than one oocyte (Grammont and Irvine, 2001). In mammals, there are four notch receptors (NOTCH1–4) and five notch ligands (jagged (JAG) 1 and 2; and deltalike (DLL) 1, 3, and 4) (Bray, 2006). Inhibition of notch signaling in cultured ovaries caused a reduction in follicle formation (Trombly et al., 2008). Loss of NOTCH 2 in somatic cells blocks nest breakdown (Xu and Gridley, 2013). In addition, deletion of ADAM10, a secretase that cleaves and activates the Notch receptor also disrupted nest breakdown and primordial follicle formation (Feng et al., 2016). The c-Jun amino-terminal kinase (JNK) signaling cascade plays important roles in many developmental processes including oogenesis. Specifically, JNK is important for nest breakdown and follicle formation as JNK inhibition disrupts these processes (Niu et al., 2016). Ovary organ culture studies have revealed additional factors with potential roles in nest breakdown. Addition of KIT ligand to developing ovaries in organ culture accelerates follicle formation, while a function blocking antibody against the KIT tyrosine

Table 1 Molecules involved in regulating nest breakdown

<i>Gene</i>	<i>Protein/function</i>	<i>Evidence for role in NBD</i>	<i>References</i>
<i>Activin A</i>	TGF β family member	Promotes follicle formation while an activin antagonist causes multiple oocyte follicles	Bristol-Gould et al. (2006) and McMullen et al. (2001)
<i>Adam10</i>	Regulator of Notch signaling	Mutants have disrupted nest breakdown and follicle formation	Feng et al. (2016)
<i>Ahr</i>	Aryl hydrocarbon receptor, basic helix loop helix transcription factor	Follicle formation is accelerated in mutants	Benedict et al. (2000) and Robles et al. (2000)
<i>Bmp15</i>	Bone morphogenetic protein 15, TGF β family member	Mutants have multiple oocyte follicles	Yan et al. (2001)
<i>E-cadherin</i>	Cell adhesion molecule	Inhibition causes premature nest breakdown in hamsters and in mice	Niu et al. (2016) and Wang and Roy (2010)
<i>Figla</i>	Factor in the germ line alpha, folliculogenesis specific basic helix loop helix	Mutants are defective in follicle formation and exhibit perinatal oocyte loss	Soyal et al. (2000)
<i>Fsh</i>	Follicle stimulating hormone, glycoprotein polypeptide hormone	Promotes follicle formation	Lei et al. (2010) and Roy and Albee (2000)
<i>Follistatin</i>	Activin antagonist	Mutants defective in follicle formation	Kimura et al. (2011) and Wang et al. (2015)
<i>Foxl2</i>	Forkhead box L2, winged helix transcription factor	Mutants are defective in follicle formation and exhibit perinatal oocyte loss	Schmidt et al. (2004) and Uda et al. (2004)
<i>Gdf9</i>	Growth differentiation factor 9, TGF β family member	Mutants have multiple oocyte follicles	Yan et al. (2001)
<i>JNK</i>	The c-Jun amino-terminal kinase	Inhibition disrupts nest breakdown and follicle formation	Niu et al. (2016)
<i>Kit signaling</i>	Kit ligand Kit receptor tyrosine kinase	Promotes follicle formation in hamsters and mice	Jones and Pepling (2013) and Wang and Roy (2004)
<i>Lunatic fringe</i>	Regulator of Notch signaling	Mutants have multiple oocyte follicles	Hahn et al. (2005)
<i>N-cadherin</i>	Cell adhesion molecule	Inhibition delays nest breakdown in hamsters	Wang and Roy (2010)
<i>Ngf</i>	Nerve growth factor, neurotrophin signaling	Follicle formation is reduced in mutants	Abir et al. (2005) and Dissen et al. (2001)
<i>Notch ligands</i>	Jagged 1 and 2	Inhibition of Notch signaling reduces follicle formation	Trombly et al. (2008)
<i>Notch receptors</i>	Notch 1 and 2	Inhibition of Notch signaling reduces follicle formation. Notch 2 mutants have defective nest breakdown	Trombly et al. (2008) and Xu and Gridley (2013)
<i>Nobox</i>	Newborn ovary homeobox-encoding gene	Mutants have delayed follicle formation and oocyte loss	Rajkovic et al. (2004)
<i>Ntrk1</i>	NGF receptor, neurotrophin signaling	Follicle formation is reduced in mutants	Kerr et al. (2009)
<i>Ntrk2</i>	Receptor for NT-4 and BDNF, neurotrophin signaling	Follicle formation and germ cell number is reduced in mutants	Kerr et al. (2009) and Spears et al. (2003)
<i>p27</i>	Cyclin-dependent kinase inhibitor 1, downstream of PI3K signaling	Follicle formation is accelerated in mutants	Rajareddy et al. (2007)
<i>Taf4b</i>	Ovary specific subunit of TFIID	Mutants have delayed nest breakdown	Grive et al. (2014)

kinase receptor inhibits follicle formation in both mice and hamsters (Jones and Pepling, 2013; Wang and Roy, 2004). Nerve growth factor (NGF) has also been implicated in primordial follicle formation. Not only do *Ngf* homozygous mutants have reduced numbers of primary and secondary follicles, they also have more oocytes not enclosed in follicles at P7 (Dissen et al., 2001). In addition, mutants of NGF receptors, NTRK1, and NTRK2, have reduced numbers of follicles lending support to the idea that NGFs are important for follicle formation (Kerr et al., 2009; Spears et al., 2003).

Mouse knockouts of several transcription factors have phenotypes suggesting roles in primordial follicle formation. Mutants in the gene encoding the aryl hydrocarbon receptor (AHR), a basic helix loop helix (bHLH) protein, form follicles at a faster rate than normal (Benedict et al., 2000; Robles et al., 2000). Factor in the germline alpha (FIGLA) is another bHLH protein (Liang et al., 1997). *Figla* mutants begin to lose oocytes at birth and oocytes still present are not enclosed in primordial follicles (Soyal et al., 2000). Disruption of *Nobox*, an oocyte specific homeobox gene results in an increased oocyte loss and a delay in nest breakdown (Suzumori et al., 2002; Rajkovic et al., 2004). Mutants in *Foxl2*, a winged-helix forkhead transcription factor, are sterile and germ cell nests are present in adult ovaries (Uda et al., 2004). Finally, mutation of TAF4b, an ovary-specific subunit of the TFIID general transcription complex results in delayed nest breakdown (Grive et al., 2014).

Cell adhesion molecules (CAMs) may be important to keep oocytes together before nest breakdown and also during nest breakdown to promote the association of primary oocytes and pregranulosa cells. Recent work using the hamster model has implicated

two CAMS, N and E-cadherin in follicle formation (Wang and Roy, 2010). These CAMs appear to have opposing roles in nest breakdown and primordial follicle assembly with E-cadherin involved in keeping oocytes together and N-cadherin important for oocyte/pregranulosa cell interactions. More recently, there is evidence from studies in the mouse that E-cadherin is important for maintaining oocytes in nests and/or cysts and must be downregulated for primordial follicle formation to occur (Niu et al., 2016).

Functions of Connected Germ Cells

Intercellular bridges provide a means of exchanging signaling molecules and other cytoplasmic contents among sister germ cells, which is essential for normal oogenesis and spermatogenesis.

Synchronization of Differentiation and Maturation

It has been observed in cysts of *Drosophila*, *Xenopus*, and mammals that germ cells connected by intercellular bridges develop in a synchronized manner. Germ cells in cysts undergo synchronized mitosis and meiosis during oogenesis in mice and rabbits (Lei and Spradling, 2013; Pepling and Spradling, 1998; Ruby et al., 1969; Zamboni and Gondos, 1968). In adult mammalian testes, the connections between genetically distinct haploid spermatids allow these cells to share the cytoplasm and hence develop equally (Braun et al., 1989). The connection in *Drosophila* male cysts facilitate the death of the whole cyst when one germ cell encounters damage in its genome, suggesting that cysts may serve a purpose of protecting genomic integrity during sperm production (Lu and Yamashita, 2017).

Nursing Mechanism During Oocyte Formation

A well-characterized function of female *Drosophila* germline cysts is to facilitate cytoplasmic transport and oocyte formation in the cyst. In the *Drosophila* cyst, asymmetric distribution of the fusome establishes polarity in the cyst that directs cytoplasmic enrichment into the oocyte through microtubule-dependent transport. The similar function of nursing in mammalian female cysts was initially suggested by studies using EM. As a canal that connects two cells, organelles including smooth ER, ribosomes, smooth vesicles, mitochondria, and microtubules can be found within the bridge in mouse, rabbit, and human fetal ovaries (Gondos, 1973; Pepling and Spradling, 1998; Ruby et al., 1969; Zamboni and Gondos, 1968). Through the observation of organelle distribution in individual germline cysts in mouse fetal ovaries, centrosomes, Golgi complexes and mitochondria were found to redistribute extensively within germline cysts during oocyte differentiation, leading to about 20% of the fetal germ cells differentiating into primary oocytes with enriched cytoplasmic content. Similar to *Drosophila*, the germ cells that donate their cytoplasm undergo apoptosis (Lei and Spradling, 2016). However, in the ovaries of primitive insects (grasshopper, cockroaches) and *Xenopus*, no significant germ cell apoptosis in cysts were observed and all germ cells develop into oocytes (Kloc et al., 2004; Pritsch and Buning, 1989).

Other Functions

Besides the above two major functions of cysts in gametogenesis, it has been proposed that cyst may serve a function of: (1) *facilitating the onset of meiosis*, given the fact that the cyst-formation cycle involves a significant alteration in the cell cycle and cyst formation always seems to precede the onset of meiosis; (2) *facilitating organelle biogenesis* through enriching mitochondria; (3) *inhibition of mitosis* to restrict the number of germ cells entering meiosis; (4) *restriction of motility* (Gondos, 1973; Pepling and Spradling, 1998; Pepling and Spradling, 2001).

Glossary

Anaphase promoting complex A complex cellular machinery that marks the target cell proteins for degradation.

Connexins Proteins making gap junctions for the transfer of molecules between cells.

Cyclic adenosine monophosphate A second messenger important in many biological processes. It is derived from ATP by adenylate cyclase enzyme. It plays key role in maintaining the meiotic arrest of oocyte.

Cyclic guanosine monophosphate A second messenger synthesized from GTP by guanylate cyclase enzyme.

Cyclin dependent kinase 1 A serine/threonine kinase that plays key roles in both mitosis and meiosis progression.

Follicle stimulating hormone A hormone synthesized and secreted by anterior pituitary gland. It regulates development, growth, pubertal development, and follicle development in the ovary.

Gap junctions Special intercellular connections between different cell types.

Ligand A substance that binds with its specific receptor and produces a signal.

Luteinizing hormone A hormone synthesized and secreted by anterior pituitary gland. It functions closely with follicle stimulating hormone for testis and ovary development.

Maturation promoting factor A complex of cyclin and cyclin dependent kinase that stimulates cell cycle progression both in mitosis and meiosis.

Phosphodiesterase 3A An enzyme that hydrolyses cyclic adenosine monophosphate.

Phosphorylation A chemical reaction adding a phosphoryl group to its substrates.

Receptor A protein molecule on or inside a cell that selectively receives chemical signal (ligand) from outside a cell.

Introduction

Meiosis is a specialized cell division consisting of two rounds of successive divisions that halves the number of chromosomes in the sperm or oocyte. Oocytes enter meiosis during fetal life but become arrested at diplotene stage of prophase I until puberty. Oocytes arrested at prophase I contain a large nucleus surrounded by nuclear envelope also known as the germinal vesicle (GV). GV breakdown (GVBD) and dissolution of the nuclear membrane is the first morphological sign of oocyte meiotic resumption. A surge of luteinizing hormone (LH) induces meiotic resumption and ovulation of the oocyte. In the follicle, the oocyte is surrounded by somatic cells called granulosa cells. The interaction of oocytes and granulosa cells is an essential aspect of reproductive biology as it is necessary for development of both the oocyte and the follicle (Fig. 1). One of the first known examples of oocyte–granulosa cell interaction provides a graphic example of this interaction; the demonstration that removal of the fully grown oocyte from the follicle into a suitable culture medium allows spontaneous resumption of meiosis completely independent of LH. We now understand the signaling mechanisms responsible for this remarkable ability of the granulosa cell compartment to maintain meiotic arrest and then transduce the LH signal to the oocyte where it triggers meiotic resumption.

Mechanism of Oocyte Meiotic Arrest: A Role for cAMP

The spontaneous resumption of meiosis that occurs when the oocyte is removed from the fully grown antral follicle provides a critical insight into the mechanism of meiotic arrest. It suggests that the somatic cells of the follicle prevent the resumption of meiosis in the oocyte and that the LH surge overcomes this inhibitory action rather than providing an independent positive stimulus. The action of LH is also dictated by the location of its receptors on the theca and mural granulosa cells (McGee and Hsueh, 2000). Thus, LH does not stimulate meiotic resumption by acting directly on the oocyte. Rather, recent evidence shows that LH stimulates meiotic resumption indirectly by disrupting intercellular communication between the somatic cells of the follicle and also between the cumulus cells and the oocyte.

A number of lines of evidence suggest that a high level of cyclic adenosine monophosphate (cAMP) in the oocyte is responsible for maintenance of oocyte meiotic arrest (Fig. 2A). Examples include, the spontaneous meiotic resumption of fully grown oocyte is prevented if oocyte cAMP concentration is maintained by adding its analog dibutyryl cAMP to the culture medium. cAMP is inactivated by an enzyme cAMP phosphodiesterase 3A (PDE3A) and inhibition of phosphodiesterases in oocytes in vitro leads to maintenance of meiotic arrest. In vivo evidence that PDE3A is the key physiological regulator of cAMP in oocytes is provided by mutant mice lacking *Pde3a*; in these mice oocytes are permanently arrested at the GV stage and never resume meiosis due to

Fig. 1 Schematic representation of mammalian ovary showing the process of follicle development. Primordial follicle contains an oocyte surrounded by flattened pregranulosa cells. It develops through primary, secondary and early antral follicle stages before forming an antral follicle containing a fluid-filled antral cavity. Within the follicle, oocytes remain arrested at prophase I and are characterized by a germinal vesicle (GV). Antral follicle contains mural granulosa cells closer to the basement membrane and cumulus granulosa cells closer to the oocyte. Follicle stimulating hormone (FSH) stimulates the development of antral follicles. A preovulatory surge of luteinizing hormone (LH) at puberty stimulates fully-grown antral follicle leading to oocyte meiotic resumption and ovulation of mature egg for fertilization. The remaining of the antral follicle becomes corpus luteum.

failure in cAMP degradation (Masciarelli et al., 2004). This indicates that regulation of PDE3A activity is a key factor in linking cAMP levels and meiotic maturation in vivo.

Further support for the cAMP hypothesis of meiotic arrest comes from interrupting oocyte cAMP production through genetic ablation of adenylyl cyclase (AC), the enzyme responsible for catalyzing production of cAMP from ATP. Mouse oocytes deficient in AC fail to arrest at GV stage in vivo and undergo spontaneous maturation in the follicle (Horner et al., 2003). The activation of oocyte AC is thought to be mediated by G-protein-coupled receptors (GPCRs) present in the oocyte plasma membrane. The GPCR activates a G-protein, Gs, known to activate AC, leading to cAMP synthesis (Fig. 2A). When the function of Gs is blocked, oocytes cannot synthesize cAMP leading to a spontaneous meiosis resumption within the follicle (Mehlmann et al., 2002; Ledent et al., 2005). Similarly, mutant mouse oocytes lacking an orphan receptor GPCR3 also resume meiosis within the follicles in vivo. Together these experiments tightly couple oocyte cAMP to meiotic resumption and suggest that oocyte cAMP is generated by an orphan GPCR coupled to AC and that this cAMP is elevated in oocytes due to repression of PDE3A.

Somatic Cells Prevent cAMP Degradation in Oocyte

Throughout folliculogenesis, bidirectional communication between oocyte and its surrounding somatic cells is essential for the coordinated development of both oocyte and somatic cells (Fig. 1). A fully grown follicle has two types of granulosa cells: those immediately surrounding the oocyte are called cumulus granulosa cells and those which line the basement membrane are called mural granulosa cells (Fig. 1). The somatic cells in the follicle are extensively connected via gap junctions, which are intercellular membrane channels that allow adjacent cells to share molecules smaller than 1 kDa. Gap junction channels are composed of proteins belonging to the connexin (Cx) family, and Cx43 is the most predominant Cx in the gap junctions between granulosa and cumulus cells while Cx37 is on the oocyte surface, presumably coupling the oocyte to the cumulus cells (Fig. 2). The major question is how this somatic cell–oocyte syncytium functions to maintain meiotic arrest by promoting an elevation of oocyte cAMP.

In a remarkable series of experiments it has been discovered that follicular cells synthesize cyclic guanosine monophosphate (cGMP) which diffuses into the oocyte through Cx37-containing gap-junctions. cGMP is a potent inhibitor of PDE3A thereby

Fig. 2 Model showing the regulation of oocyte meiotic arrest and the resumption of meiosis upon puberty onset. (A) Oocyte meiotic arrest at GV stage requires the synthesis and maintenance of high levels of cAMP, which is produced via the activation of the GPCR/Gs/AC pathway in oocyte. A high cAMP level is maintained in the oocyte by preventing its degradation by inhibiting PDE3A. Mural GCs produce Nppc, which stimulates the generation of cGMP by Npr2 (a guanylyl cyclase) present in cumulus GCs. cGMP enters the oocyte via Cx37 containing gap junctions and prevents PDE3A from hydrolyzing cAMP in the oocyte. cAMP activates PKA that in turn activates the Wee1B kinase and inhibits the Cdc25B phosphatase leading to the inactivation of CDK1. Also shown in the figure is the constantly degraded cyclin B1 (cycB1) that prevents MPF activation in prophase I-arrested oocytes. (B) A preovulatory surge of LH upon puberty onset causes closure of gap junctions throughout the follicle halting the supply of cGMP to the oocyte. This in turn increases cAMP hydrolysis by PDE3A. Low levels of cAMP and PKA can no longer activate Wee1B and inactivate Cdc25B and Cdk1 becomes dephosphorylated and catalytically active. Active Cdk1–cycB1 complex causes the GVBD and meiotic resumption. P—phosphorylation. Modified from Adhikari, D. and Liu, K. (2014). The regulation of maturation promoting factor during prophase I arrest and meiotic entry in mammalian oocytes. *Molecular and Cellular Endocrinology* **382**, 480–487.

allowing the endogenous oocyte AC activity to drive up cAMP levels (Fig. 2A) (Norris et al., 2009; Vaccari et al., 2009; Conti et al., 2012). These observations further helped to dispel the hypothesis that meiotic arrest is maintained by cAMP diffusing from the somatic compartment and established cGMP as the critical somatic compartment messenger that is essential for maintaining meiotic arrest.

The guanylyl cyclase activity for synthesizing the cGMP from GTP is mediated by natriuretic peptide receptor 2 (Npr2) which is expressed on cumulus cells (Zhang et al., 2010). Furthermore, the stimulation of Npr2 on cumulus cells is mediated by natriuretic peptide precursor type C (Nppc) secreted from mural granulosa cells (Fig. 2A) (Zhang et al., 2010). As such, genetic studies show that oocytes from either *Npr2* or *Nppc*-null mice cannot sustain meiotic arrest in vivo (Zhang et al., 2010).

Taken together, these findings provide a clear understanding of how the oocyte is maintained in meiotic arrest in the follicle but the question remains as to how the LH surge overrides this arrest and initiates the resumption of meiosis in the oocyte.

Puberty and Meiosis Resumption: Overcoming cAMP-Mediated Arrest by LH

Before puberty, the fate of follicles starting to grow is to die by atresia. After puberty, the secretion of pituitary-derived gonadotrophins and the maturation of the hormonal reproductive cycle mark the initiation of ovulatory reproductive cycles. This increase in gonadotropins allows the growth and survival of only a limited number of antral follicles that reach to the preovulatory stage (Fig. 1) (McGee and Hsueh, 2000). In response to a complex interaction of follicle stimulating hormone (FSH), ovarian regulators, and growth factors it is usual that one (in human and monovular species) or several (in polyovular species) follicles grow faster and establish dominance so as to become the preovulatory follicles. In response to the preovulatory LH surge, changes in the follicle compartment lead to the oocyte within the dominant follicle(s) resuming meiosis, and undergoing ovulation as a mature oocyte prepared for fertilization (Fig. 1) (McGee and Hsueh, 2000).

The LH surge is known to promote substantial changes in gene expression in granulosa cells, which leads to a cascade of changes that indirectly promotes oocyte meiotic resumption. A key trigger is that LH causes the breakdown of gap junctions throughout the

follicle thereby halting the supply of cGMP from somatic cells to the oocyte (Fig. 2B). When the cumulus cells stop supplying cGMP to the oocyte, the activity of PDE3A enzyme increases leading to cAMP hydrolysis and the resumption of meiosis (Norris et al., 2009; Adhikari and Liu, 2014; Zhang et al., 2010). The model for LH-mediated oocyte meiosis resumption is presented in Fig. 2B. In support of this model, LH stimulation of rat granulosa cells in vitro can mediate the phosphorylation and decrease in the expression of Cx43 leading to the disruption of the gap-junction communication between the granulosa cells. In order to test whether the closure of gap junctions alone is sufficient for oocyte meiotic resumption, follicle-enclosed oocytes from rat were treated with a chemical known to block the gap junctions. Blocking of gap junctions indeed reduced cAMP concentrations in the oocytes and caused resumption of meiosis in follicle-enclosed oocytes (Sela-Abramovich et al., 2006).

Several LH-induced signaling pathways are responsible for these dramatic changes in the follicle that ultimately lead to meiotic resumption in the oocyte. The most upstream pathway identified is the rapid induction of expression of epidermal growth factor (EGF)-like factors. Such factors include epiregulin, amphiregulin and betacellulin, all of which show a dramatic increase in expression within 3 h of LH stimulation. In vitro, when these EGF-like growth factors are added to the cultures of cumulus–oocyte complex or follicles, they activate EGF receptor (EGFR) on somatic cells and promote oocyte meiotic resumption. These events are mediated via the EGFR activation because they are inhibited by small molecule inhibition of EGFR (Park et al., 2004). In vivo, the physiological roles of EGF-like growth factors in LH-induced oocyte meiosis resumption have been demonstrated in mutant mouse models. LH-induced Cx43 phosphorylation and gap junction closure is impaired in mutant mouse models with inactivating mutations of EGFR (Conti et al., 2012). Thus the evidence indicates that LH-induced EGFR activity stimulates oocyte meiotic resumption by causing the closure of gap junctions and decreasing cGMP production in the follicle.

In addition to EGF-signaling pathways, LH also induces a dramatic increase in activity of the mitogen activated protein kinase (MAPK) pathway. Disruption of MAPK signaling in mouse granulosa cells prevents the LH-induced resumption of oocyte maturation (Fan et al., 2009). In fact, MAPK is a major downstream regulator of the EGF-like growth factors because they can no longer stimulate oocyte meiosis resumption in cumulus–oocyte complex if the cumulus cells are lacking MAPK. The requirement for MAPK appears to be in its ability to interrupt cell-to-cell communication among mural and cumulus cells through phosphorylating connexin 43. Thus, LH-induces a coordinated signaling cascade in the follicle causing decreased cGMP production and a breakdown in gap-junctions that ultimately starves the oocyte of cGMP. The resultant release of PDE3A activity allows a decrease in oocyte cAMP and release of meiotic arrest.

These discoveries of the last decade have unlocked a long-standing question in reproductive biology; that of how the follicle cells and hormonal signals interact in order to coordinate oocyte maturation with ovulation so as to ensure successful fertilization. Concurrently, the question of how cAMP interfaces with the cell cycle machinery that control the biochemical pathways of meiotic arrest and resumption were being uncovered.

Signaling From cAMP to the Cell Cycle Machinery That Drives Meiotic Resumption

During cAMP-mediated meiotic arrest it is essential that the activity of maturation promoting factor (MPF), a complex of cyclin dependent kinase 1 (CDK1) and its regulatory subunit cyclin B1, remains low (Adhikari et al., 2012). Suppression of MPF activity is ensured by inhibitory phosphorylation of CDK1 (Adhikari et al., 2016) and maintenance of a stable level of cyclin B1 through a steady rate of regulated proteolysis (Reis et al., 2006; Marangos et al., 2007). The inhibitory state of CDK1 is maintained by Wee1B/Myt1 kinases and its activation requires dephosphorylation by the phosphatase Cdc25B. The critical nature of this kinase–phosphatase pair is demonstrated in experiments in which they are specifically deleted from growing oocytes. In Wee1b knock out oocytes there is induction of spontaneous resumption of meiosis while Cdc25b knock out oocytes fail to resume meiosis in response to LH.

The effector kinase of cAMP, protein kinase A (PKA) acts as the critical pivot for suppressing CDK1 activity, phosphorylating and activating Wee1B kinase (Han and Conti, 2006) and at the same time providing inhibitory phosphorylation of Cdc25B phosphatase (Pirino et al., 2009). Thus cAMP–PKA activity takes a belt and braces approach to maintain CDK1 inhibition (Fig. 2A) activating the inhibitor and inhibiting the activator.

In response to the LH surge the subsequent decrease in oocyte cAMP drives an increase in Cdc25B activity and a release of Wee1B-mediated inhibition. This allows Cdc25B-mediated removal of inhibitory phosphates on CDK1 and the resultant increase in CDK1 activity drives the resumption of meiosis. Having been released from what may have been many years of arrest at prophase I of meiosis, the oocyte is released from the shackles of cAMP and progresses under translational and posttranslational modifications to proceed through meiosis I to metaphase of meiosis II, where it again arrests, awaiting fertilization to drive the transition from oocyte to embryo.

Conclusion

The generation of eggs or ova involves a specialized type of cell division called meiosis, which occurs in oocyte over a prolonged period of time. Although the oocyte enters meiosis during fetal life, it becomes arrested at the diplotene stage of the first meiotic prophase until puberty. Extracellular stimuli, mainly generated by surrounding granulosa cells control meiosis arrest and resumption of oocyte. In particular, cGMP synthesized in the granulosa cells inhibits the activity of CDK1/Cyclin B1 through maintaining high cAMP levels in oocyte. LH activates several signaling pathways in the granulosa cells that disconnects the oocyte

from its surrounding granulosa cells by closure of gap junctions. Without the supply of cGMP from granulosa cells, the oocyte cannot maintain high levels of cAMP and as a result undergoes meiotic resumption. A number of pathways modified in granulosa cells after LH stimulation have been reported and the list of such molecules is increasing. However, the ovarian follicle, being a complex tissue and technically challenging to study, only yields mechanistic data on how the signaling pathways interact to orchestrate oocyte meiosis after many years of intensive investigation. An improved understanding of how the LH surge drives the resumption of meiosis in oocytes will help us to treat female infertility that results from oocytes that fail to resume meiotic maturation.

Oocyte Maturation During Folliculogenesis

Teresa K Woodruff, Hoi C Lee, Jaewang Lee, and Maxwell Edmonds, Northwestern University, Chicago, IL, United States

Introduction

Fertility in the female is determined by the developmental competence of the oocyte, specifically its ability to undergo growth, meiosis, fertilization, and produce a healthy embryo (Kidder and Vanderhyden, 2010). The mammalian ovarian follicle is composed of a single oocyte, one or more layers of adjacent and surrounding somatic cells (granulosa cells), and a marginal rim of theca cells separated from the granulosa cells by a basal lamina (Fig. 1; Araujo et al., 2014). During folliculogenesis, a number of primordial follicles grow and develop into pre-ovulatory follicles. Preovulatory follicles contain a grown oocyte, capable of maturing into a fertilizable oocyte through both hormonal regulation, stimulation by the gonadotropins follicle stimulating hormone [FSH] and luteinizing hormone [LH], and bi-directional oocyte–somatic cell communication through gap junctions.

Oocyte Maturation From Primordial Through Growing Follicles

The ovary has a number of different stage of follicles which are classified by the number of granulosa cells in the largest cross section of each follicle as proposed by Pedersen and Peters (1968). In mammals, a finite and maximum number of oocytes is present at birth, which decreases throughout the female lifespan. These oocytes are initially arrested in the diplotene stage of prophase I of the meiosis I from fetal life throughout childhood until puberty, when LH surges stimulate the resumption of meiosis. During folliculogenesis, the diameter of the ovarian follicle and oocyte gradually increase across time; as confirmed in the mouse, hamster, pig and human as shown in Fig. 2 (Griffin et al., 2006).

Before primordial follicles initiate their growth and development, they are “activated” by currently unidentified factor(s) from their surrounding environment. These factor(s) might include nutrients, oxygen tension, and other signaling molecules. Activation stimulates for oocyte growth, leading to extremely large amounts of mRNA transcription and protein translation (Liu et al., 2006). At this time, the primordial follicle relies on the bi-directional between oocyte–somatic cell gap junctions, in order to fuel their fast development.

Oocyte Maturation Through Ovulation

The mammalian oocyte is arrested as a diploid cell ($2n$) with $4c$ DNA during prophase I of the first meiotic division, which occurs during the oocyte growth phase. Ovulation is triggered by the LH surge, which in turn is triggered by increasing levels of estradiol secreted by the pre-ovulatory follicle. Before LH surge stimulation, cyclic guanosine 5'-monophosphate (cGMP) travels through gap junctions from the surrounding somatic cells into the oocyte. cGMP is produced by the transmembrane guanylyl cyclase natriuretic peptide receptor (NPR2). The NPR2 is present in all granulosa cells, although is not present in the oocyte. cGMP inhibits the degradation of another cyclic nucleotide called cAMP in the oocyte. This high level of cGMP in the oocyte inhibits the hydrolysis of cyclic adenosine 3', 5'-monophosphate (cAMP) by the phosphodiesterase 3A (PDE3A), and maintains a high level of cAMP, which blocks meiotic progression. The PDE3A, an antagonized enzyme by cGMP, primarily affects cAMP. After the LH surge just before ovulation, the gap junctions between the oocyte and the cumulus cells (immediately adjacent somatic cells) are closed, and cGMP begins to decrease in the oocyte, relieving the inhibition of PDE3A. This causes a decrease in oocyte cAMP, re-enabling the meiosis process (Norris et al., 2009). Metaphase I then initiates, as an orchestrating of the nuclear membrane breaking down (germinal vesicle breaks down) and chromosomes condensing into bivalents and aligning on the meiotic spindle. The homologous chromosomes segregate and one set are extruded in the first polar body, while the other remains in the oocyte. Meiosis is then arrested again until the oocyte has been fertilized (Shuhaibar et al., 2015).

The LH surge leads not only to resumption of meiosis and nuclear maturation, but also to cytoplasmic maturation and the maturation of the zona pellucida, a protective outer layer of the oocyte. This cytoplasmic maturation includes the migration of cortical granules to the outer cortex of the oocyte, a reorganization of the endoplasmic reticulum, an increase in the number of 1,4,5-inositol triphosphate receptors, and an increase in the concentration of calcium ions in the endoplasmic reticulum. LH also stimulates the transformation of the follicular mural cells from estrogen producing cells, into progesterone producing cells. LH also stimulates local prostaglandin production and the enzymatic digestion of the follicular wall, leading to its rupture (ovulation), releasing the cumulus–oocyte complex from the follicular wall. When released from the follicle, the cumulus–oocyte complex stays near the ovarian surface and is picked up by the fimbriae of the fallopian tube (Strömstedt and Byskov, 1999).

Meiosis

Meiosis is the unique cell division that reduces the number of chromosomes in germ cells. It consists of two separate divisions, which end in the production of haploid gametes. The major difference between mitosis and meiosis is the segregation of chromatids.

Fig. 1 Schematic sequence of a complete follicular development. Oogonia develop from a primordial germ cell and differentiate into an oocyte in the ovary. All the pre-antral follicles have a primary oocyte which is diploid/46 (2N), containing 4 chromatids arrested in diplotene of prophase I. The pre-ovulatory stage is the last stage of follicle development; these follicles have increased antral fluid and may contain a secondary oocyte.

Fig. 2 Follicle and oocyte growth during folliculogenesis in different mammal. Semi-log bar graph of follicle diameter versus follicular stage. * indicates values from previously published data for reference, and therefore do not include error bars. Values are the mean $\pm$ standard error.

Pre-meiotic DNA synthesis produces 4C DNA, with a chromosome number of $2n$, as in normal diploid cells. The first meiotic division, meiosis I, begins with prophase I. In the first meiotic prophase a unique exchange between the maternal and paternal genes takes place. This occurs as homologous chromosomes are separated into daughter cells because the centromere does not divide as in mitotic divisions. The two daughter cells thus contain $1n$ chromosomes and $2c$ DNA and are prepared with different genetic constitutions. The first meiotic prophase consists of four successive stages defined as leptotene, zygotene, pachytene, and diplotene stages. During the leptotene, zygotene, and pachytene stages the homologous chromosomes line up and condense gradually. In the pachytene stage, a synaptonemal complex is produced, allowing for normal segregation of the chromosomes in the first meiotic division, which takes place at the time of ovulation. In the diplotene stage, the chromosomes decondense. Interestingly, the nuclear membrane is present throughout the first meiotic prophase. When the oocyte reaches the end of meiotic I prophase, the meiotic process stops, and the oocyte remains in the diplotene stage until it is either excluded by atresia, undergoes apoptosis, or succeeds in reaching the maturation and resumes meiosis during ovulation. The second meiotic division, meiosis II, is a mitotic division of each of the haploid cells and resembles a normal meiotic division without DNA synthesis; the sister chromatids separate and segregate. As a result, haploid oocytes have $1n$ chromosomes and $1c$ DNA, and all four daughter cells are haploid and genetically different. The second meiotic divisions in oocytes are asymmetric, resulting in the formation of one large oocyte and small polar bodies. Therefore, only one egg cell results from the two meiotic divisions in the female germ line (Strömstedt and Byskov, 1999).

Cumulus Cell Expansion

During the pre-ovulatory period, the cumulus–oocyte complex (COC) expands, preparing for meiotic maturation and enabling developmental capability. Cumulus cell expansion is dependent on extracellular matrix synthesis by cumulus cells. Hyaluronic

acid is the most plentiful component of this extracellular matrix, and synthesized from glucose through the hexosamine biosynthesis pathway. Cumulus expansion occurs during meiotic oocyte maturation. During oocyte maturation, cumulus expansion is thought to influence a variety of essential processes supporting the oocyte's development. After the LH surge, granulosa cells produce EDF-like factors that act on cumulus cells to induce cumulus expansion and oocyte maturation. EGF receptor expressed on cumulus cells up-regulates the ERK1/2-dependent pathway. The signaling pathway plays important roles in oocyte meiotic maturation and cumulus cell expansion because cumulus cells regulate oocyte growth and oocyte maturation (Shimada, 2009).

Glossary

Actin-related protein 2/3 (Arp2/3) Arp2/3 is a conserved protein complex of actin-related proteins ARP2 and ARP3, which enucleates branching actin filaments.

Asymmetric cell division Asymmetric cell division is a characteristic of female meiotic maturation in which the smallest daughter cell, the polar body, is designed to degenerate, safeguarding all the organelles and molecules within the larger cell—the oocyte.

Cytoplasmic streaming Cytoplasmic streaming is the movement of actin, organelles and the fluidic cytoplasm in a coordinated pattern. In large cells, such as the oocyte it can be the most important means of reorganization and intracellular transportation.

Germinal vesicle breakdown (GVBD) The germinal vesicle (GV) is the name used for the nuclear envelope in an oocyte. At the initiation of meiotic maturation, this nuclear envelope is disassembled, a process similar to the somatic cell nucleus. GVBD is essential, prior to spindle formation and completion of meiosis.

Microtubule organizing centers (MTOCs) MTOCs are the sites of microtubule nucleation and anchoring. In somatic cells, these would be the centrosomes. However, in mammalian oocytes, meiotic spindles lack centrioles and therefore they do not have true centrosomes. The MTOCs are maternally inherited and used by the oocyte until after fertilization, when embryos assemble centrioles either denovo or contributed from the sperm.

Transzonal projections (TZPs) TZPs are long extensions from the cumulus cells that stretch through the zona pellucida and contact the oolema. These projections contain an actin and/or tubulin cytoskeleton and gap junctional pores that allow for direct intracellular communication between the oocyte and its companion cumulus cells. These connections are essential. The cumulus cells provide molecules to both nourish the oocyte and to maintain meiotic arrest. In turn, the oocyte sends signals to the cumulus cells indicating that the oocyte is healthy and maintains the cumulus in a quiet state. The surge in luteinizing hormone (LH) during the estrous cycles causes the gap junctions to close, preventing exchange of molecules from the cumulus and oocyte, thus triggering oocyte maturation.

Zona pellucida (zona) The zona is a thick extracellular matrix that surrounds the oocyte and physically separates the oocyte from its companion cumulus cells. The TZPs extend from the cumulus cells through this matrix to maintain contact and to communicate with the oocyte.

Introduction

The oocyte's size and function make it a unique cell within the animal kingdom. Even though oocytes and spermatozoa (sperm) contribute an equal number of chromosomes to the zygote, the oocyte alone contributes the cytoplasmic stockpile of molecules and organelles needed throughout the long developmental and maturation process of oogenesis (Li and Albertini, 2013; Coticchio et al., 2015). The last step in oocyte maturation is in fact very fast and occurs immediately before ovulation, triggered by the maternal surge in LH (Li and Albertini, 2013; Coticchio et al., 2015; Plancha, 1996).

The oocyte begins its journey as a primordial germ cell migrating from the allantois to the genital ridge, where it differentiates into an oocyte (McLaren, 2003). Oocytes enter meiosis and arrest in diplotene of prophase-I (PI) of meiosis-I (MI), while still interconnected by inter-cytoplasmic bridges and surrounded by somatic cells forming the oocyte clusters of the ovigerous cords. Follicle formation, the acquisition of flattened granulosa cells, occurs after birth (rodents) or during fetal life (human) coinciding with cluster breakdown and major germ cell loss. The primordial follicles stay in a quiescent state throughout reproductive life until the oocyte undergoes nuclear and cytoplasmic maturation to accomplish fertilization (Peters and McNatty, 1980). Growth from primordial to preovulatory follicle is regulated by endocrine and paracrine, as well as intra- and inter-cellular communication. Bidirectional communication between oocyte and the cumulus cells surrounding it is fundamental (Li and Albertini, 2013; Rodrigues et al., 2008) and requires maintenance of intact TZPs extending from the somatic cumulus cells to the oocyte cell surface (oolema) (Albertini et al., 2001) (Fig. 1B, white arrow). The TZPs provide the means for dialogue between somatic and germ cells, maintaining meiotic arrest, while enabling development of the oocyte cytoplasm and its stockpile of molecules and organelles; maternal contributions that will be required for processes of oocyte maturation, fertilization and embryo development.

Fig. 1 Transzonal processes (TZPs) and GV maturation. (A and B) An intact cumulus-enclosed GV stage oocyte that has been release from a large antral follicle and stained with fluorescently labeled molecules that identify DNA (blue) and F-actin (white). At this stage prior to the LH-surge, the cumulus cells tightly enclose the oocyte, but are physically separated from it by the zona (B, yellow arrows). To maintain critical communication with the oocyte, the cumulus cells project through the zona to contact the oocyte cell surface. These processes can be visualized by staining for actin, which forms the cytoskeleton of the TZPs (A and B, white). Nuclei are seen as blue in (A and B); in (B), the blue are the nuclei of the cumulus cells. (C and D) Demonstrate two phases of GV maturation, the NSN configuration (C), and the SN configuration (D). The GV can have a single or multiple nucleoli (C, red asterisk; D, white asterisks). The GV in (D) is an enlargement of the nucleus from the oocyte in (A; note white asterisks that identify the nucleoli in both images). Images were taken on a Zeiss LSM Pascal scanning confocal microscope. Each image is 10 μm thick. White bars show scale: (A) 10 μm , (C and D) 5 μm). Actin labeled with phalloidin. DNA labeled with Hoechst 33258.

Oocyte maturation is the stage of meiotic progression from PI to metaphase-II (MII) and first polar body extrusion. This event involves carefully orchestrated and rapid changes in cytoskeletal organization, organelle redistribution, and membrane polarization. In this chapter, we will focus on the structural aspects of oocyte maturation.

Nuclear Maturation

While arrested in PI the oocyte nucleus is called the germinal vesical (GV). It is large and centrally located within the oocyte cytoplasm. It contains a prominent nucleolus with condensed heterochromatin or diffuse euchromatin (Albertini, 2015). The nuclear envelope of the GV has pores, allowing and mediating RNA trafficking during the oocyte growth phase. In human oocytes, chromatin remodeling is linked to meiosis resumption (Combelles et al., 2003; Escrich et al., 2010). Specifically, chromatin is transformed from diffuse (non-surrounded nucleolus, NSN; Fig. 1C, asterisk) to a perinucleolar and heterochromatin state (surrounded nucleolus, SN) (Miyara et al., 2003) (Fig. 1D, asterisk). This transition occurs in the fully-grown oocyte during antral follicle formation and is considered an early sign that the oocyte is ready to begin meiotic maturation. Oocytes that reach an SN configuration have higher developmental potential than NSN oocytes (Luciano et al., 2012). Communication with cumulus cells

is essential for the transition from NSN to SN chromatin configuration, evidenced by the arrest of the oocyte in GV stage if cultured without granulosa/cumulus cells (De La Fuente and Eppig, 2001). This cumulus cell communication likely occurs via gap junctions between the TZPs and oolema, as indicated by the failure of chromatin remodeling in the oocytes of female mice with connexin 37 gene deletion, which is an oocyte specific gap junction protein (Carabatsos et al., 2000).

According to its chromatin configuration, the GV has also been further classified into four stages: GV0 to GV3. Global DNA methylation is associated with the increasing condensation of the DNA and is also implicated in the acquisition of meiotic and developmental competence (Luciano et al., 2012). GV0 chromatin is diffuse and filamentous throughout the nucleus. GV1 is an early stage of chromatin remodeling, where the chromatin appears as a few foci of condensation, which progress to distinct clumps of chromatin condensation in GV2, an intermediate stage. The highest level of chromatin condensation is achieved at GV3, with all chromosomes clustered together, immediately prior to spindle formation. Noteworthy, GV0 oocytes have lower capacity to resume and complete meiosis, while GV1-3 oocytes, regardless of configuration stage, will all mature to MII stage in vitro. However, developmental competence of these oocytes is affected by GV stage: GV2 and GV3 oocytes can develop to blastocyst stage after in vitro fertilization, whereas GV1 have much less developmental potential under the same conditions (Luciano et al., 2012). This progressive chromatin condensation within the intact GV is the earliest stage of oocyte meiotic maturation and is associated with oocyte developmental competence.

The LH surge triggers oocytes to exit from PI arrest, initiate germinal vesical breakdown (GVBD), and begin MI spindle assembly (Fig. 2). Depending on species and external conditions (in vivo versus in vitro), the MI spindle forms in the center of the oocyte. However, the spindle needs to be eccentrically located, just under the oocyte cytoplasmic membrane to ensure that cytokinesis occurs with minimal loss of cytoplasm. One set of chromosomes will be expelled from the oocyte into a small polar body—extremely asymmetrical division (Dalton and Carroll, 2013; Yi et al., 2013).

Formin-2 (Fmn2) is an actin-nucleating protein expressed in oocytes and is required for progression through MI. This has been demonstrated in mice lacking Fmn2 in which, despite normal karyokinesis their oocytes fail to extrude a polar body (Leader et al., 2002). Recently it was suggested that Fmn2 together with Arp2/3 regulates MI spindle relocation (Yi et al., 2013). In brief, the endoplasmic reticulum (ER) vesicles recruit Fmn2 to the periphery of the spindle. This polarized distribution of Fmn2 causes the spindle to drift (Peters and McNatty, 1980; Leader et al., 2002). This drifting leads to Arp2/3 activation in the proximal cortex that triggers cytoplasmic streaming, which pushes cytoplasmic contents away from the cortex while also pushing the spindle towards the cortex (Peters and McNatty, 1980; Leader et al., 2002) (Fig. 2, red arrows). When the metaphase chromosomes move near to the oolema, F-actin and Arp2/3 are activated and a dense layer of actin forms in the cortex directly above the spindle (Longo and Chen, 1985; Yi et al., 2011). In fact, it has been shown that cortical actin polarization adjacent to the spindle is required for maturation (Coticchio et al., 2014). Moreover, disruption of actin in mouse oocytes leads to both larger GV's and enlarged MI spindles (Barrett and Albertini, 2010) underscoring the importance of actin in maintaining proper oocyte structure. An enlarged MI spindle causes a larger polar body (Plancha et al., 2005), leading to reduced cytoplasmic mass in the MII oocyte, which may compromise the early embryo development (Coticchio et al., 2015).

The actin-driven asymmetric position of the meiotic spindle is not the only difference between the spindle of the oocyte and the somatic cell spindle. The mammalian meiotic spindle lacks astral microtubules. Since the oocyte has no centriole-containing centrosome, it has microtubule organizing centers (MTOCs) instead (Li and Albertini, 2013; Maro et al., 1986; Messinger and Albertini, 1991) (Fig. 2, green asterisk). These MTOCs contain γ -tubulin and pericentrin similar to somatic cell centrosomes, and can be seen as foci within MTOCs and at the spindle poles (Li and Albertini, 2013). In the mouse, γ -tubulin has been implicated in oocyte spindle and polar body position and size (Barrett and Albertini, 2007). Reserves of γ -tubulin and its allocation to specific subcellular sites is vital to early embryonic progression, as shown by embryo developmental arrest when maternal γ -tubulin is absent (Yuba-Kubo et al., 2005).

Fig. 2 Oocyte nuclear maturation.

Cytoplasmic Maturation

Cytoplasm, also known as ooplasm, is composed of basic cellular organelles including: endoplasmic reticulum (ER), Golgi apparatus (GA), lysosomes, ribosomes, mitochondria, and annulated lamellae, which are similar to those found in all somatic cells. In addition, cortical granules (CGs) and Balbiani's body are organelles unique to oocytes (Albertini, 2015). Here we will focus on the organelles that are critical for oocyte maturation (Fig. 3).

Mitochondria contribute directly to oocyte metabolic demand providing most of the energy required for oocyte maturation, fertilization and early embryo development. Structurally, the maternal inheritance of mitochondria begins during primordial follicle formation when the mitochondrial founder population is established in the ooplasm of these cells (Combelles et al., 2003). Typically, mitochondria are situated perinuclear and associated with the Balbiani's body in the arrested oocyte (Li and Albertini, 2013). As the oocyte grows, the mitochondrial population amplifies steadily. The mitochondria change in abundance, location and function during maturation, and provide the energy needed for the reorganization of the cytoskeleton and other organelles (Albertini et al., 2001). Mitochondrial-DNA (mtDNA) replication occurs throughout oogenesis, but it stops completely in the fully-grown oocyte; only later, in the developing embryo, is it resumed. The mitochondria are an interesting example of selective migration during maturation which prevents their loss into the extruding polar body. At MI, mitochondria congregate near the MI spindle and migrate with the spindle to the oocyte cortex. But with the initiation of anaphase, the mitochondria segregate towards the spindle pole furthest from the cleaving polar body and thus are retained within the larger oocyte during cytokinesis (Combelles et al., 2003). Mitochondria are also sites of calcium storage, although the primary organelle responsible for cytoplasmic calcium regulation is the endoplasmic reticulum (ER).

The ER stores and releases free Ca^{2+} in the cytoplasm and is required for intracellular calcium oscillations that trigger both meiotic maturation to MII and the completion of meiosis at fertilization (Ducibella and Fissore, 2008; Cheon et al., 2013). ER distribution differs between the GV stage and MII oocytes and is visibly polarized. The GV ooplasm contains ER clusters that are not well defined and are scattered throughout the ooplasm with larger clusters in the interior near to the GV. However, by the MII stage, the ooplasm has developed a reticular network of ER extending over the entire ooplasm with large aggregates at the cortex (reviewed in Coticchio et al., 2015). The ER, by recruiting Fmn2 to the spindle periphery, is also involved in the cytoplasmic streaming of actin and organelles, as seen above (Yuba-Kubo et al., 2005).
